Stillé says: "When either of the mild preparations of mercury are given in small but repeated doses, with a view of affecting the system, peculiar phenomena are developed. The first appreciable effect is usually an increased activity of the secretions, particularly of the intestinal canal, the discharges from which become liquid and bilious. The mucous membrane of the respiratory apparatus, and sometimes also of the genito-urinary or-

[1] Read before the New York Obstetrical Society, November 2, 1887.

gans, display a similarly augmented secretion. If there happen to be anywhere an interstitial deposit of fibrine, or a collection of serum, its absorption is promoted."[1] This statement embodies my belief regarding the physiological action of calomel when given in mild doses. It was this understanding of the matter which induced me, several years ago, to array myself among those who advocate the administration of this salt in *diphtheria*. I believe it is the best remedy we possess with which to combat this dread affection. It not only meets the indications according to its powers depicted by Stillé, but, in harmony with more recent ideas regarding its properties, it offers us succor in accordance with our modern conception of diphtheria. That is to say, it is one of a very few safe and effective germicides with which we can saturate the system, and, according to Keys, it is tonic.

My experience with diphtheria is not as extensive as that of some who are listening to me; indeed, it is surprisingly small. But from the manner in which the calomel has served me, since I began its exclusive use, I am impelled to call your attention to it.

I have now treated thirty cases by this method—26 children and 4 adults—and have lost two children. One child, aged four years, who had progressed without an unfavorable symptom, was allowed to walk across the floor, and died from heart-paralysis immediately afterward. Another, aged two and a half years, an inmate of the New York Infant Asylum, had rachitis, hydrocephalus, talipes of both feet, and chronic diarrhœa, and died last night from laryngeal stenosis, having been sick only three days. Within two weeks I have had eleven cases of diphtheria at the New York Infant Asylum, and have depended wholly upon calomel and whiskey. The disease was always detected in its first stage, and our treatment has in every instance, except two, caused rapid resolution of the patch and prevented the invasion of the larynx. The two exceptions were the rickety child which died, and a little fellow, aged eighteen months, who recovered. This latter child had laryngeal deposits following the invasion of the fauces. Obstructed and noisy breathing ensued, and the calomel was increased from one-sixth grain to one-third grain every hour. The next day the patient was much better, the respiration being quiescent, except when the child cried or became excited. That night, however, hoarseness, with rapid and very labored breathing, supervened. The calomel was increased to one grain every two hours, and after five hours there was great improvement in every symptom, and the case has gone on to advanced convalescence. We have been compelled to push the medicine in doses equalling one grain every hour, for a period of five hours, in several cases, and no untoward results have manifested themselves, except perhaps in one case, where vomiting came on, and the temperature rose to 104° F. I was disposed to regard this as mercurial fever, for the symptoms subsided when the medicine was stopped. In no instance have I observed anything like salivation, and, to my surprise, except in the rachitic boy, who already had chronic diarrhœa, the bowels never were inordinately affected, even under the largest doses. Three movements a day were the average.

I trust it is not necessary that I should apologize for this discursive paper. Nothing original is claimed. I want to hold fast to that which is good, and, if possible, induce others to do the same. I have purposely omitted all references and lists of names of those who have either advocated or disparaged the use of the mild chloride of mercury in the affections enumerated. It would have added nothing to the value of the paper, for everybody knows that there have always been two sides to this question. My object is simply to rehearse my experience, to declare my practice, and to elicit from those more versed and abler than myself their views upon the subject discussed.

I claim for calomel that it is the best and most agreeable cathartic for children; that it is a markedly antiseptic and tonic medicine; that it is an effective diuretic; that it promotes dissolution of fibrinous formations, whether they be interstitial or whether they be membranous deposits upon mucous surfaces.

A CASE OF POTT'S DISEASE WITH AN UNUSUAL DEFORMITY—DESCRIPTION OF IMPROVED SPINAL APPARATUS.[1]

By HENRY LING TAYLOR, M.D.,
NEW YORK.

The patient whose history I will relate was an unmarried lady, twenty-nine years of age. Father and mother are living, but there is phthisis on the paternal side. Patient was always delicate and easily tired. She had whooping-cough when a baby, after which a cervical gland suppurated; she had measles at nine years. In the summer of 1882 the patient began to have severe pains low down in or near the sacrum, which would be aggravated by walking. In the autumn the mother noticed that the right hip was higher than the left. Then the patient began to hold the shoulders stiff and would stiffen the back when stooping; and had to lie on the left side without moving when in bed. In October, 1882, the patient was obliged to go to bed on account of the severity of the pain, where she remained until February, 1883. While in bed the pains disappeared and the lateral inclination of the back to the right became less.

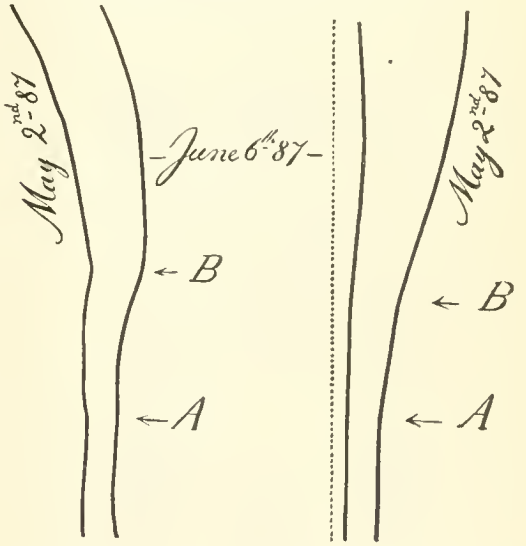

Fig. 1. Fig. 2.

After that she grew rapidly worse; the pains, which extended at times to the right side, across the hips, and down the thighs, became so severe as to twice compel her to go to bed for several months. While resting in bed she would feel better, and on again attempting to go around she would get worse. Her general health suffered very much, and she was sent to Florida in October, 1885, supposed to be suffering from phthisis. She was somewhat drawn over to the right side.

In August, 1886, a swelling appeared in the left lumbar region, which was opened in January, 1887, by her physician, Dr. J. D. Fernandez, Jacksonville, Fla., who had already diagnosed Pott's disease, and a large quantity, estimated at a quart, of light-colored, thin pus evacuated. The patient had had fever before this and it continued some time; indeed, the patient thinks she was not quite free from it until within a very short time of consulting me, April 26, 1887. In December and January she had cough and dyspnœa, but no expectoration.

When seen by me she looked extremely cachectic, and

[1] Case related and apparatus shown at the meeting of the American Orthopædic Association, New York, June 15 and 16, 1887.

suffered severe pain in the sides and low down in the back. She had been dressed and sat up a little daily since February 1st, but she walked a few steps only, with the greatest difficulty, leaning on someone's arm, and bent over extremely to the right.

Examination showed a small prominence at the eleventh dorsal vertebra, first noticed last January, and another at the third and fourth lumbar, noticed four years ago. These are shown at the left of Fig. 1. There was a sinus discharging pus in the left loin. But what was most striking was the extreme lateral bending of the spine at the two foci of disease, amounting together to over fifteen degrees deviation from the vertical (shown at the right of Fig. 2). The distance from the iliac crest to the axilla was two inches greater on the left than on the right side. This lateral deformity had been a marked feature of the case from the beginning, and was noticed before the posterior projection.

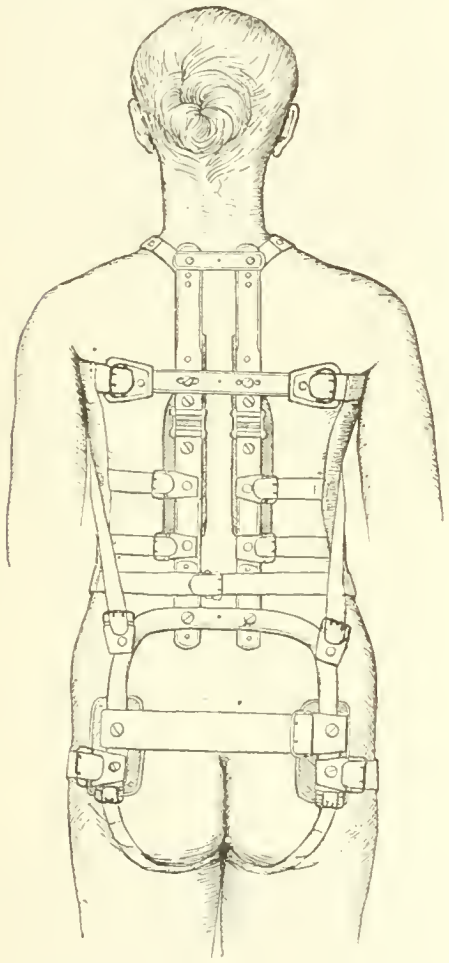

Fig. 3.

Lateral deviations of moderate, and sometimes considerable, extent, due to unequal erosion of the two sides of the vertebral bodies, are not uncommon, especially in the earlier stages of the disease, low down. Indeed, as was pointed out in the discussion following the relation of this case at the meeting of the American Orthopædic Association, in early lumbar caries lateral tilting of the spine without rotation may be a valuable diagnostic sign.

These lateral deviations ordinarily yield to the antero-posterior protective support which is demanded by the other indications of the disease, and is not a troublesome complication. This case presented, however, such unusual features that I was at first quite in doubt what plan of support would be most efficient. I finally decided to employ Dr. Taylor's improved antero-posterior leverage spinal apparatus, which I will presently describe; but to fit it to the back I was obliged to curve the vertical bars over to the right to correspond to the lateral contour of the spine. There was no lateral action in the apparatus except the slight pulling of the left perineal strap, which I buckled tighter than the right. The patient was put to bed. The pain disappeared in a few days, and the patient began to improve in health. Considerably to my surprise, the lateral distortion at the end of a month was trifling, as shown by the line nearest the dotted vertical in Fig. 2. The line to the right of Fig. 1 shows the antero-posterior contour at the end of the same time. The patient has gone on gaining up to the present time, and now walks around with considerable freedom. The abscess discharges considerably less, and there has been marked improvement in the general health.

The interesting points in this case are the excessive degree of tilting at two points, with very moderate antero-posterior deformity, and the predominance throughout of lateral distortion; also its rapid subsidence under adequate protective treatment.

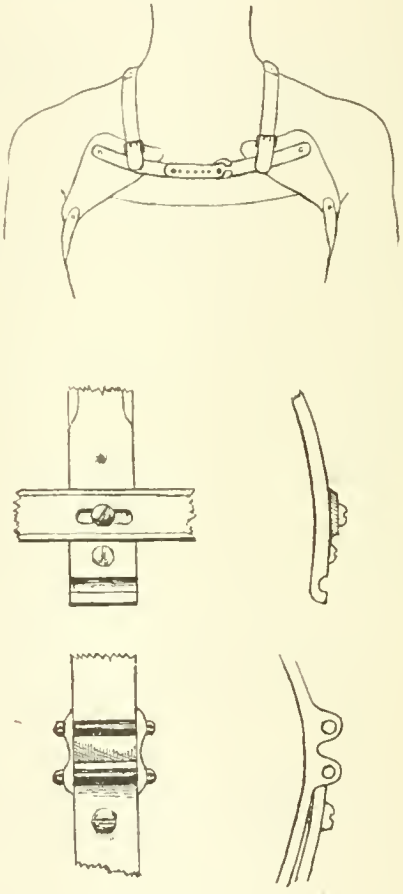

Fig. 4.

The apparatus devised by Dr. C. Fayette Taylor, over twenty-five years ago,[1] for the treatment of Pott's disease, and figured and described (often incorrectly) in surgical works, has in the last fifteen years undergone considerable modification and improvement in the way of definiteness and precision of action, though the principle of antero-posterior leverage remains unchanged. As the perfected instrument has never been authoritatively described, I thought it might be of interest to the profession to exhibit a cut of it, and indicate the points in which it differs from the apparatus generally known by Dr. Taylor's name.

The apparatus shown (Figs. 3 and 4) is the form which has been in use in Dr. Taylor's private practice for twelve years or more.[2] It differs from the apparatus shown to the New York State Medical Society in 1863 in the following points: 1. The parallel vertical bars

[1] Shown at the meeting of the New York State Medical Society, Albany, February 3, 4, and 5, 1863.

[2] Apparatus like the one figured, and adapted to the different regions of the spine, were exhibited at the Centennial Exhibition, Philadelphia, 1876.

have been lengthened, and end in hooked pieces passing well over the shoulders near the neck. 2. The hinges differ somewhat in construction (see detail Fig. 4) and are screwed to the bars, being retained solely for the purpose of facilitating modification of the apparatus corresponding to the varying indications of the case. 3. The horizontal hip band is discarded, and replaced by a rigid steel bar having the shape of an inverted U; to the upper part of this band the lower ends of the vertical bars are firmly attached. The ends of the U-shaped band are fitted into the post-trochanteric sulcus on either side, and together with the hooked pieces at the root of the neck fix the apparatus laterally, besides assisting in antero-posterior and vertical fixation. The lower ends, being points of contact with the skin, are protected by hard rubber plates. 4. Hard rubber pads are used instead of the soft pads formerly employed, to transmit the leverage of the apparatus to the region of the spine which it is desired to protect. 5. Instead of the straps encircling the arm formerly used to get a fixed point for counter-force in front, a "chest-piece" is employed, consisting of two ear-shaped or triangular hard rubber pads, fitted under the clavicles and resting on the pectoral muscles, and joined by a stiff steel bar, curved forward to escape the chest, and so contrived that the distance between the plates may be increased or diminished at will. The chest-piece being in position, is buckled to straps coming from the ends of the shoulder-hooks above, and below it is strapped to a buckle at the angle of the U-hip-band on either side, thus leaving the arm free and the axilla untouched. See upper part of Fig. 4. 6. The apron which holds the whole apparatus forward reaches to the posterior border of the axilla on either side, and from the trochanter to the arm laterally, and is secured by straps and buckles to the apparatus.

It is to be understood, of course, that appropriate modifications of structure of the apparatus are made for disease in the different regions of the spine, and for the character and amount of the deformity. Most cases of disease above the sixth or seventh dorsal will require Dr. Taylor's circular pivoted head-support, which is easily fitted to this apparatus. The different points alluded to are shown in the cuts.

NOTHNAGEL ON THE OERTEL METHOD FOR THE TREATMENT OF HEART DISEASE.—In a recent clinical lecture on the treatment of heart disease, Professor Nothnagel said that he considered the method of Oertel superfluous and even inadmissible in cases of compensation of valvular affections of the heart, or in affections of the cardiac muscle, when there is no degeneracy present, as each excitation of the heart had to be avoided in that period. The different authors were of the same opinion as to the part which the reduction of liquid food played in that method, but the good results obtained by it in heart diseases were due to the methodical ascensions which were executed by the patients, and there was much reason to believe that these ascensions augmented the cardiac action and the energy of the myocardium. When a muscle was irritated twice a day for some minutes, an augmentation of the volume and the weight of the muscle was obtained after some time, a fact of which Professor Nothnagel had been able to convince himself by experiments performed for about a year and a half. The same was true of the cardiac muscle; the hypertrophy of the heart in valvular affections was produced by mechanical conditions, and owing to this hypertrophy there took place a compensation of the circulating disturbances. As, however, the hypertrophy did not exceed a certain degree, the muscle thus hypertrophied soon became degenerated, and a new stimulant was necessary for hypertrophying it again. The methodical ascensions prescribed in the method of Oertel played the part of such a stimulant, but they had to be carefully watched by the attending physician.

AN INTERESTING CASE OF HYSTERICAL AMBLYOPIA IN THE MALE.[1]

By S. BARUCH, M.D.,

VISITING PHYSICIAN TO THE NEW YORK JUVENILE ASYLUM AND MANHATTAN HOSPITAL;

AND

EDWARD S. PECK, M.D.,

VISITING SURGEON TO CHARITY HOSPITAL, AND CONSULTING SURGEON TO THE OUT-DOOR DEPARTMENT OF BELLEVUE HOSPITAL.

THAT hysteria may occur in the male, as well as in the female, is now an accepted fact. Although to our colleagues of recent date it would seem that the dictum could scarcely be disputed, we, who sat in the college benches a quarter of a century ago, realize how difficult it has been to the medical mind to emancipate itself from the etiological idea which has been perpetuated by that misnomer hysteria. We know to-day that hysteria has no more connection with the uterus than with any other organ, not even with the now fashionable ovary. It happily appears that a gradual, and, I trust, steady, emancipation from the exclusively sexual etiology of hysteria is now developing. The uterus has been so much abused in the search for causes of hysteria in its various disturbances; its erosions have been cauterized; its versions and flexions have been corrected to such an extent, that a reaction is now upon us. How little do we now read in the journals of new pessaries and supporters. At our last meeting this skepticism on the subject of pessaries manifested itself decidedly.

Rarely is the speculum ever now used by the skilled physician, especially in multiparous women, in whom hysterical manifestations are so frequent. But our gynecologists have discovered another *bête noir*, the ovary. Since Charcot called attention to his "ovarie"—the iliac pain as a predominating symptom of hysteria—his eloquent and masterly work has born sad fruit, and I am glad to see that in the Berlin Medical Society, this idea received a fatal blow from such men as Landau, Gusserow, and the lamented Carl Schroeder, two years ago. Landau, I may say in parentheses, brought before the Society a case which appeared to be a complete illustration of Charcot's idea, and in which pressure upon the left iliac region produced severe pain and hysterical symptoms, but in which, after removal of the ovary, the pain and hysteria continued in full sweep.

Normal ovariotomy—oöphorectomy—has been described as a panacea for all otherwise intractable hysterical women. How often the operation fails will probably never be known; but this much is already certain, that the future holds in store for the enthusiastic oöphorectomist the same disappointments which the past has conferred upon the energetic ante-versionist and ante-flexionist. A great neurologist and alienist (Mendel) has told us that the alienists are in the best position to discover the damage done to nervous women by the gynecologist, whom he calls the Mephistopheles with the speculum.

Far be it from me to deny that we may frequently discover in utero-ovarian diseases sources of ill-health from which originate severe hysterical manifestations. But I desire to emphasize the point, that too much attention has been, and is still, directed by medical men to the sexual organs of women as well as of men, and that the introspection incident to this attention has aggravated the sufferings of our patients and diminished the effect of our therapeutic measures.

The case I am about to relate is an illustration of the same result arising from the eye.

The lesson to be deduced from the history of medicine is, that hysteria is a functional disease of the general nervous system, which has its origin in psychical influences connected or unconnected with physical disturbances, and that inasmuch as all elements which depreciate

[1] Read at the Stated Meeting of the Northwestern Medical and Surgical Society, May 18, 1887.

the general health contribute to the maintenance of hysteria, these physical disturbances should be sought out and *removed when they are clearly productive of health depreciation.* The frequency of hysteria in the male has been only recently brought into prominence, chiefly by French physicians, probably due to the national mental characteristics of the Frenchman, whose nervous and volatile temperament predisposes him to these disturbances. It is a singular fact that out of 77 reports of hysteria in the male, catalogued in the Surgeon-General's Library, 35 are rendered by French authors, and only 3 by Germans, the remainder being by Italian, English, and American physicians. Briquet found among 1,000 cases 50 in the male; Petit reports 61 cases in 1875, and Fère 77 cases in 1877. Still the disease is so interesting that probably nearly every pronounced case finds publication. To these I will add the following.

Mr. X——, aged twenty-one, of good physique and healthy parentage, no other hereditary neurotic influence, consulted me last fall with regard to epileptic attacks from which he had been suffering seven years. The attacks had been quite frequent, of the *grand-mal* type, and, despite active treatment by many physicians, they had not yielded until he came to this city. He was placed in an institution, in which a regular mode of life, substantial but coarse food, and strict supervision of all his movements, together with small doses of bromides, improved his general health greatly. He gained flesh and became buoyant and hopeful, until one day in October he was unhappily aroused from his sense of security by a severe attack. I now subjected him to a thorough physical examination, which revealed the fact that his former attendants had endeavored to remove all recognizable causes of reflex irritation. An inguinal hernia had been supported by a truss, the meatus urinarius had been split *secundem artem*, his bowels had been regulated. In my search for some undiscovered source of reflex irritation I discovered a deviated septum nasi, to which was attached the lining membrane of the opposite turbinated bone on the left side, and a greatly swollen and erectile turbinated lining in the right nasal fossa. I shrivelled the latter with the galvano-cautery point, and for treatment of the former I sent him to my friend, Dr. Bosworth, who skilfully removed the obstruction, thus affording him free nasal respiration. Removal of the inferior turbinated swelling has, according to Hack, cured epilepsy.

For two months the patient remained free from attack, although not receiving any medication. About this time his father was brought to the city in a dying condition. He was an anxious and devoted attendant upon him. He lost much sleep, and later became greatly depressed by the death of his father. One week after the latter event he had a severe convulsion while asleep. He was now put under the bromide with Fowler's solution. A month elapsed and another attack occurred, and again another. He now became alarmed and depressed. He had entertained great hope from the nasal treatment, because he was cognizant of a case of epilepsy in a boy, from whose left nasal fossa I had removed an enchondroma growing from the septum, with the result of complete and lasting cessation of the fits.

A week after his last attack he consulted me regarding a form of amblyopia, which, owing to its anomalous character, aroused my suspicion of a hysterical origin. He insisted that all objects appeared greatly magnified, that his vision was clear, but that bright light blinded him, and the enormous proportion of objects, whose size he knew perfectly well, annoyed him greatly. His mother apprehended that the usual disturbance was due to the medicinal treatment he was receiving. But even after cessation of the latter, the symptoms increased and others were added, for the diagnosis of which I referred him to my friend Dr. Peck.

On the afternoon of his visit to Dr. Peck, to whose kind interest I feel much indebted, patient called with the doctor. It appeared that the careful examination of his refraction, and the effort to obtain an ophthalmoscopic observation resulted in an aggravation of his symptoms. He now complained of intense hyperæsthesia of the eyeball and orbital ridge. A slight touch of the brow made him exclaim and shiver with pain. Numerous sensitive points were also discovered on the cheek. Taking into consideration the fact that the patient had recently experienced a great mental shock, in the death of his father, and believing that this shock had been much enhanced by the disappointment due to the failure of the nasal operation, to which he had fondly looked for complete relief from his terrible affliction, attention was directed to the probability of a hysterical seizure.

The anomalous visual manifestations which, during his morning visit were not so pronounced, had been magnified in the patient's mind by the thorough, and, to him, novel investigation of the oculist. Alarmed by finding himself so deficient in vision, his mind had brooded over the impending calamity, so that when he reached my office at 5 P.M., he looked a changed man; his countenance was haggard, and his whole expression one of melancholy despair.

It was not difficult now to elicit any desired reply to leading questions. Thus pressure upon various points along the spinal column elicited expressions of intense pain, and this was produced whether the pressure was deep or simply a pinching of the skin was resorted to. Sir Benjamin Brodie has taught ("On Hysterical Knee") that the pathognomonic sign of this trouble is furnished by the fact that pinching of the skin will give rise to the same pain as deep pressure. I have frequently resorted to this method of differentiating an hysterical from an inflammatory affection. In October, 1882, I was called to see a young lady by the late Marion Sims, who had operated on the cervix by posterior section, and in whom the right knee presented pronounced symptoms of pyæmic trouble. Brodie's sign eliminated pyæmia at once, and not only relieved the patient and attendants from alarm, but pointed out the treatment. Dr. H. Marion Sims will remember this case.

In the case before Dr. Peck and myself, the Brodie method pointed so clearly to hysteria that no doubt remained in our minds that patient was suffering from a well pronounced case of hysterical amblyopia in the male.

Treatment was directed accordingly. He had adopted the use of smoked glasses to protect his eyes against the bright light. These were gradually changed to a lighter hue. Elix. valer. ammon. was advised every two hours, alternating with milk-punch. He was ordered to take a plunge into cold water every morning, to be followed by violent friction of the body. The chief element in the treatment, however, was psychical. During the latter part of our consultation, the first portion of which had been conducted in German, the patient was permitted to hear our conversation. We intentionally spoke in his hearing with great confidence of his early recovery, and when I afterward addressed him in the same vein, assuring him that there was no doubt of his rapid recovery, provided he pursued the treatment conscientiously, he expressed confidence in this opinion and groped his way out of my office.

Two days later he reported progress; the eyes could tolerate light more readily, the magnifying impression had decreased, his whole demeanor indicated a lifting up from a state of great mental depression to one of buoyant hope.

The cold plunge was continued, stimulants discontinued, and another dose of cheer was administered. Four days later patient returned in a perfectly normal condition.

NOTES BY DR. PECK.

Mr. X——, aged twenty-one years, was sent to me by Dr. Baruch, April 6, 1887, for examination of his eyes. I found him highly excitable, somewhat erratic, and intense in his desire to hear and know the worst. He

stated that he had been an epileptic since boyhood; but that since November, 1886, he had had no convulsions and only two seizures. In that month a deviated septum had been successfully removed by Dr. Bosworth, and up to that time patient had been taking thirty grains potassium of bromide, and four gtt. of Fowler's solution three times a day. He stated that he had had at long intervals a nocturnal emission, but he had never masturbated. Three days ago, or on April 3d, while visiting a relative, in company with his mother, he became suddenly blind, and his vision was so far reduced that he was obliged to feel his way home; at that time he was able to see better by night than by day. On his visit his eyes were somewhat congested and staring; on my handling his lower lid he complained of severe pain, while touch of the upper lid was not painful. The eyeballs were exceedingly sensitive to the touch, though there was no increase of tension. Further examination of the skin revealed marked hyperæsthesia below a line subtended from one external canthus, over the ear-tips, to the other canthus, through the eyeballs, and crossing the nasal bridge; a touch upon the skin or hair below this line threw the immediate part into a spasm; a touch above this line instantly after exhibited no special reflex.

The upper cervical spine was also hyperæsthetic. Vision in each eye was about equal to finger-counting at three feet; for distant vision there was no improvement with either a + or — glass. In the darkened room, with the feeble illumination of an argand burner, there was homonymous diplopia to the left. The distance between the images, he stated, was about two feet. With this diplopia there was an uncertain amount of dyschromatopsia; that is to say, the light to the right was the natural yellow sodium flame, while the light to the left was light blue. However, when colored glass slides were placed before the eyes color-perception was accurate, the diplopia still existing; red, blue, and yellow, of various shades were accurately perceived and differentiated. As to the diplopia, I am convinced that there was no malingering; for it required a prism of 12°, base outward, to fuse the images; one of 10°, as also one of 14°, caused the diplopia to continue, though in a less marked degree—that of 10° nearly fusing the double lights; that of 14° giving crossed images which he was able to describe. Hemiopia existed for each eye; for the right the outer half had visual perception; for the left eye, the inner half. I found it absolutely impossible to use the ophthalmoscope, both because the eyes were hyperæsthetic, and because forcible pressure on the lids produced pain; however, a second's glance in the right fundus revealed nothing abnormal. The opinion was given that it was amblyopia, due to hysteria or to hystero-epilepsy, the diagnosis hitherto entertained by Dr. Baruch. A cold plunge, one minute every day, the elix. valer. ammon., and smoked glasses which had been used were ordered continued, but of a lighter hue.

I saw the patient one week later, on April 13th, when every symptom of hyperæsthesia, amblyopia, diplopia, etc., had disappeared; vision in each eye was $\frac{20}{15}$, or better than normal; and for near vision Jaeger's type No. 1 was read at 5 to 18 inches without any + lens. The fundus of each eye was positively normal.

A few remarks upon this case are pertinent. The special points to be noted are the sex of the patient, the paracranial line of demarcation of hyperæsthesia, and the hemiopia. The retinal excitability, diplopia, and amblyopia are more general symptoms in the clinical course of an hysterical amaurosis.

I find by consulting the Index-Catalogue of the Library of the Surgeon-General, also three German journals—one of which has been devoted to ophthalmological literature for over thirty years—several English and French journals, and several of the larger text-books, that the literature of this subject is meagre, and that it runs into channels of more decided neurological investigation. The cases of pure hysterical amblyopia in the male have been rare; usually there are complications like these: Peripheral paralysis or affections of single nerve-branches, extensive anæsthesias of the skin and mucous membrane, hemiplegia—partial or total—with disturbance or loss of taste and smell, local hyperæsthesias of different parts—especially in the ovarian region or at the points of exit of nerves—hysterical convulsions of different kinds, etc.

Among modern writers on this subject Galezowski, Charcot, and Landolt have contributed most. The older literature of the whole subject of amaurosis is fully alluded to in "Mackenzie on the Eye," and a most valuable compend it is.

Galezowski[1] is, however, incorrect in stating that prior to 1866 no mention of true hysterical amblyopia is found, and also that he reported the first case of this affection, in 1865, that of a young girl in the Hôtel Dieu. I find that Mr. Hocken published a series of papers in 1839–41, in the *London Lancet*, on this subject, which were more fully elaborated in 1842 in the *Edinburgh Med. and Surg. Journal*.[2] In these papers he early combats the doubt, then existing, as to whether amaurosis can be specified as hysterical when perfect vision is found at other times in such eyes.[3] As early as 1820 Mr. Lessey[4] describes, at length, a case of hysterical amblyopia, with the electrical phenomena in the eyes since called *phosphenes*, though he does not give this definite diagnosis to his case.

I might add here that hemiopia and hemianæsthesia usually concur in these cases, and that the hemiopia is generally on the same side of the body as the hemianæsthesia. In the case here presented there was no hemianæsthesia, and no form of paralysis or paresis of any local or regional part of the body. In a summary of 400 cases of hysteria Briquet found 93 hemiplegic; and of these 93, 73 had troubles of sight.

Galezowski[5] has so pertinently formulated the visual troubles in simple hysteria, or in hystero-epilepsy, that I shall represent them here. They are: 1, Monocular amblyopia; 2, true or simulated binocular amblyopia; 3, spasms of ocular muscles, or hysterical diplopia.

A word in regard to the seat of lesion, which has never yet been accurately determined, and I will close this clinical note. Wollaston was the first to offer an explanation of its pathological seat. On the theory that only the internal fibres of the optic nerves cross each other, he locates the lesion at the points of decussation; Michel, with whose experiments in Erlangen I am personally cognizant, believes that both the external and internal fibres of the optic nerves cross at the chiasm; while Charcot holds that only the internal fibres can be said to properly cross each other, while the external give a few filaments to the internal fibres, then pass into the tubercula quadrigemina, and finally regain the internal fibres of the opposite side.

Todd and Carpenter hold that the centre of sensibility is in the optic tract, and draw conclusions which apparently explain with precision the correlation of hemianæsthesia and amblyopia. But, after all, is the seat of general sensibility found in the optic tract?

Landolt[6] has written a very elaborate paper, in which are produced the clinical notes of many interesting cases found in Charcot's clinic. Most of these cases had disturbances of the central field of vision, shrinkages of peripheric vision, loss of and imperfect color-perception, etc. Charcot was able to make several autopsies, chiefly of cases where death was due to serious neurotic lesions. He found the seat of lesion to be a cerebral apoplexy in the domain of the posterior optic tract, or in the posterior part of an optic thalamus; his opinion that this is the probable seat of the lesion in hystero-epilepsy is amply justified by general symptoms, and confirmed by the analogy of ocular symptoms.

A CASE OF CONGENITAL HERNIA OF THE ABDOMINAL VISCERA AND LEFT LUNG—PRESENTATION OF THE HERNIAL SAC, LEFT ARM, AND SHOULDER—PODALIC VERSION.[1]

By A. M. JACOBUS, M.D.,

ATTENDING PHYSICIAN FOR DISEASES OF WOMEN, NORTHWESTERN DISPENSARY, NEW YORK, AND INSTRUCTOR IN GYNECOLOGY, NEW YORK POLYCLINIC.

Mrs. L——, aged twenty-four, primipara, and pregnant since last menstruation, December 16, 1886, enjoyed good health, but suffered from morning sickness throughout pregnancy. By advice of friends Mrs. L—— was in the habit of taking long walks, daily, until term. During the last two months of pregnancy she experienced much pain, at intervals, in the right uterine region, and also a "pressure on the stomach." On two occasions the pains were very severe, and she thought labor had commenced. On September 15, 1887, nine months after last menstruation, the patient was awakened at 5 A.M. by a sudden and profuse discharge of water from the vagina. Water, mixed with blood-clots and fæces, continued to flow at intervals during the day, and though the patient was urged to walk about, pains did not commence until after 7 P.M. the same day. I was then sent for, and upon arrival found the patient walking about the room and complaining of severe pain in the right side at each recurrence of the labor pains. The patient stated that the fœtus had been very active up to 3 P.M., but since that time no movements had occurred. An examination per vaginam revealed the cervix widely dilated, and protruding from it, to the left, the left arm of the fœtus, and to the right a large mass, or sac. The amniotic fluid had entirely escaped from the uterus, the latter being firmly contracted around the fœtus. The head could only be made out by external palpation, and was found above the brim, to the left. The body was directed obliquely upward to the right. The mass, or sac, could not be satisfactorily diagnosed, as the vagina was small and the patient disinclined to permit a thorough examination. It felt something like a placenta, with some fluid in a portion of the membranes. At first, owing to the history of free hemorrhage during the day, placenta prævia lateralis was suggested to my mind. Later, when the patient permitted a better examination, such a condition was excluded, as no uterine attachment could be made out, while the mass, or sac, was found to extend well up into the uterus and appeared to be connected to the child. As the patient was very intractable and would not allow any manipulation toward correcting the abnormal presentation, anæsthesia was suggested and readily consented to. Dr. Alexander S. Hunter kindly came to my assistance, verified the conditions as reported, and administered chloroform. As attempts to push up the arm, or bring down the head, failed, podalic version was decided upon. Owing to the obliquity of the child and the contracted condition of the uterus, version was a difficult task. When the legs were brought down the sac ruptured. As the hips presented externally, a dark mass also protruded from the vagina. This proved to be, to my surprise, a mass of intestines.

The delivery of the shoulders was difficult, owing to the presence of a body twice as large as a door-knob, which also occupied the vagina. This proved to be the fœtal liver. The head soon followed the delivery of the shoulders, and then our suspicions as to a malformed child were confirmed. The body was in a condition of complete right lateral curvature of the spine. This was probably due to the oblique position in which the fœtus had been carried, and the hernia of the abdominal viscera. On close examination it was found that there was an absence of the abdominal wall of the fœtus to the left of the umbilicus, and extending to the sternum and ribs. This opening was fully two and a half inches in diameter. The sac previously mentioned was attached around its border, and was slightly larger than a pint measure. It was translucent, excepting at its border, where it was opaque and gradually merged into true skin. The wall of the sac was composed of two layers, probably peritoneum and amnion. The abdominal cavity was almost void. From the opening the fœtal stomach, intestines, liver, spleen, left kidney, and fundus uteri were completely extruded. The diaphragm was also lacking on the left side, and there was an opening into the left pleural cavity through which the lung protruded. The heart was displaced to the median line, below the sternum, but was covered with integument. The placenta appeared to be normal, and came away with the umbilical cord, which had been torn from the fœtus in the delivery. Its original attachment to the umbilicus and liver could be seen. The liver was enlarged and quite round. The child had a full-sized head, but the body was undersized, and the whole weighed, nine hours after delivery, four and a half pounds. After confinement the family was questioned, and, excepting the possible effects of the long daily walks, no cause for the peculiar condition could be found. There had been no maternal impressions, and the mothers of the patient and her husband had each given birth to a number of healthy and sound children.

The patient received no vaginal injections until after the fifth day, but was washed externally, as necessary, with a weak carbolic solution. There was no rise of temperature, and she was about the house, as usual, in ten days. The breasts were bandaged tightly from the time of delivery, and anointed night and morning with hot lard. Excepting a slight tumefaction on the third day, there was no disturbance or secretion of milk. The case is unique and interesting, owing to the difficulty in making a diagnosis, as well as the complicated position and delivery.

A RARE CASE OF NEUROSES, SIMULATING MALARIAL-INTERMITTENT FEVER, DUE TO URETHRAL IRRITATION.

By A. F. SAMPSON, M.D.,

GALVESTON, TEX.

In Otis' work on "Stricture of Male Urethra," p. 304, we find M. Civiale thus quoted: "Independent of its local sensitiveness, the urethra possesses another kind, which may be termed sympathetic. . . . When this sensitiveness is aggravated, it may awaken sympathetic responses in every organ and function of the body."

That the question of neuroses due to urethral reflexes is one of grave importance to the physician, as well as the surgeon, the following case demonstrates:

William S——, German, aged eighteen, presented for treatment, June 14, 1886. Two years since came direct from Baden Baden to Galveston, Tex. He has resided in a healthy portion of this city; has been engaged in a bakery that has good sanitary surroundings. He has never been subjected to a malarial atmosphere. In November, 1885, he began to experience a marked form of tertian-intermittent fever. Every second day, without interruption, about noon, he would have a chill, followed by fever which terminated in a few hours with a profuse sweat. He had been under the treatment of two regular physicians for this intermittent fever, that was diagnosed as malarial; besides, the patient had taken quite a quantity of antiperiodic nostrums—all without avail. On inspection he presented more the appearance of one suffering from neurasthenia than malarial toxæmia. The physical examination revealed neither splenic nor hepatic enlargement.

On further examination my attention was attracted by the small meatus urinarius. The patient frankly admitted that he had been addicted to the habit of masturba-

tion from the age of fifteen to seventeen. I passed a small bulbous sound, which revealed a firm stricture half an inch from meatus, also an exquisitely sensitive urethra.

This examination of his urethra developed a constitutional disturbance similar to his chills and fever, which he stated he had been having every other day since November, 1885, though he had taken at least two bottles of quinine. This determined the trouble to be a neuroses, due to reflex urethral irritation, that simulated malarial fever. As a primary step in the treatment of this case, June 15th, under cocaine anæsthesia, I performed meatotomy and internal urethrotomy, closely observing the Otis precepts for these operations. The calibre of the urethra was restored to 34 mm. The subsequent treatment is the daily passage of a 34 mm. straight conical sound. The result was all that could be desired. From the date of the operation there was not a single return of his malarial symptoms, and the patient was rapidly restored to good health. That I might fully test my convictions as to the etiology of this case, I withheld all antiperiodics for about one week, when I gave drachm-doses of Fellows' syr., t.i.d., more as a general tonic than an antiperiodic. I have made repeated observations of this patient during the year following his treatment, to find that he has maintained good health, with a normal urethra.

When we consider with what avidity the profession seizes upon the cicatricial formations in the cervix uteri to explain the vague disturbances in the female economy, it truly seems that we have been somewhat indifferent in recognizing the analogous conditions in the male.

Clinical Department.

PULMONARY EMBOLISM (?) OCCURRING DURING GESTATION.

Dr. A. G. Browning, of Maysville, Ky, reports the following case: "Mrs. T——, aged thirty-three, fine physique, with tendency to fat; eight months advanced in fourth pregnancy. Dr. W. B. A. McNutt had been called twelve or fourteen hours before, finding patient suffering general unrest. There was some dyspnœa; the kidneys were doing satisfactorily, but the bowels had not moved for past three days. He secured free evacuation of the bowels, prognosing relief. This, however, did not follow, the main symptom—dyspnœa—even increased, and heart-failure becoming marked and obstinate he asked for a consultation. I found patient with anxious expression, slightly incoherent, exclaiming loudly of inability to get her breath; pulse vibrating between 100 and 120, very small and feeble; temperature sub-normal; mottled surface and cool extremities, with some œdema of the legs; pupils slightly dilated but responsive to light. Baring the chest the respiratory movements, though hurried, were normal and aeration seemed fair. Auscultation developed only a rather prolonged expiration, with commencing mucous râles. There were no valvular lesions of the heart manifest; the impulse was, however, markedly feeble and diffuse; fœtal pulsation was extinct, and no movements had been felt for twenty-four hours. Vaginal touch revealed usual condition at about eighth month

"Counting fœtus out, and not stopping to very accurately define things, we sought to 'obviate the tendency to death' by meeting the one indication present—support of the failing heart. Digitalis, ammonia, opium, brandy, etc., were given to support the failing heart, and external heat was diligently applied, only to fail. The cardiac pulsations grew weaker; respiration became jerky and superficial; temperature fell; pulmonary stasis with cyanosis and coma came on, and the patient died twelve hours after my first visit. She had passed no urine during the period of my attendance, but did so freely a short time before.

"As stated, this lady carried much surplus fat, and inquiry developed that within two months she had accumulated rapidly—became so burdened as to render movement laborious, causing great fatigue and a measure of dyspnœa. Her daily habit was shaped accordingly, verging upon a wholly inactive life. Her complaints were lightly treated by friends, and attributed to her condition. No professional advice was sought, and she gravitated to her end as described, without suspicion of danger till the explosion came.

"I risked the diagnosis of this case as thrombosis of pulmonary artery. 'Risked,' because a diagnosis in these cases, often obscure and difficult, was peculiarly so in this. One authority (Ball) claims that the condition cannot be distinguished during life. It was especially difficult, because the habit of the patient was the reverse of that in which the accident usually occurs, for a time invalidating the idea of thrombosis, because of the existing gestation, during which state it is extremely rare.

"In support of this diagnosis I cite the comparatively undisturbed respiratory movements and absence of developed abnormal heart-sounds, which, with increasing dyspnœa, are suggestive, if not distinctive—the mode of death by slow but progressive asphyxia, indicative of obstructed pulmonic circulation; and that in the subdivisions rather than in the main pulmonic trunk.

"I attempt no positive explanation of the mechanism. Possibly it was due to an excess of fibrin—this to hypernutrition induced by the pregnancy—giving rise to thrombosis; an embolus, somehow detached, was washed into the current, and hence the mischief. Or, more specifically, if, as Virchow affirms, there is a peculiar defective formation of the vascular system induced by gestation and puerpery, predisposing to endocarditis, it may have been embolism from this lesion—from fibrin thus deposited and broken up by the increased demand for cardiac force

"Whatever the modus the case to me is rare, as occurring during gestation—rare in comparison with the same accident in puerpery, and so far interesting."

TREATMENT OF ŒDEMA OF THE LUNGS.

Dr. P. F. O'Hanlan, of this city, sends the following communication: "A man, suffering from the last stages of phthisis, was admitted to the Gouverneur Hospital during my term as house-surgeon to that institution. The day following his admission he began to manifest symptoms of œdema of both lungs. I was sent for by the orderly. The man was dying. His respiration was hurried and labored; his face cyanotic; his pulse rapid and feeble. Cups were applied on both front and back of the chest. No relief was given by this means. It was at this minute that the idea entered my head to turn the man flat on his chest, and to allow his head to hang downward. I did this. No sooner was it done than the serum flowed from his mouth and nose. About one ounce in all escaped thus. After a few minutes the signs of œdema vanished. Whiskey was given to support the heart, I then left the patient, being obliged to go away from the hospital on business. When I returned, some ten hours after, I was informed that the man had died during my absence. He had lived for six hours, and then gotten up the œdema and died. The visiting physician of Gouverneur Hospital saw this treatment of a patient under my care, and he expressed the opinion that had it been resorted to sooner, the life of the sufferer might have been prolonged. I do not know to what extent the practice may be carried, but I think that if by this means a life can be extended, it would be only fair to give it a trial."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 19, 1887.

CARCINOMA OF THE LARYNX, AND THE CROWN PRINCE'S CASE.

ACCORDING to the latest cable-reports, there is little room for doubt that the throat-trouble from which the Crown Prince of Germany is suffering, whatever the original disease may have been, is now carcinoma of the larynx. Even Mackenzie himself, who for a long time contended—and his opinion was strengthened by the positive assertions of Virchow—that the trouble was merely a papilloma of the vocal cords, is reported to have admitted the cancerous nature of the growth. The diagnosis may therefore be regarded as settled, and the medical interest of the case is now centred on the questions of prognosis and treatment.

The prognosis of carcinoma of the larynx is, of course, fatal, though the duration of life after the appearance of the new growth varies within pretty wide limits. Thus, of the twenty-seven cases collected by v. Ziemssen, nine, or thirty three per cent., died within the first year, fifteen died between the first and the sixth years, and three lived longer than six years, one being alive even fifteen years after the disease had first manifested itself. Epithelioma is more rapid in its progress than encephaloid cancer, the average duration of the former being, according to the statistics of Fauvel, twenty-three months, while that of the latter is three years. It is possible, therefore—even should the royal patient refuse to submit to an operation—that he may yet live to reign over the German Empire, though the accession of Prince William—an event which the lovers of European peace seem to fear so greatly—can hardly, in any event, be long delayed.

It is most probable, however, that an operation of some sort will be performed within a very short time, for it is unlikely that the Prince will refuse to follow the united counsels of his physicians. Of the operations proposed there are but two, viz., tracheotomy and laryngectomy. The former is, of course, merely palliative, but its utility in prolonging life is unquestionable. It removes the danger of suffocation attendant upon the continued growth of the neoplasm, and it also seems to exert a favorable influence upon the progress of the disease by giving rest to the larynx, and affording to the patient a measurable degree of comfort, as far, at least, as his respiration is concerned. It also permits of local applications being made to the seat of the disease. According to Fauvel's experience, tracheotomy adds twenty-five months to the average duration of life in epithelioma of the larynx, and nine months in encephaloid disease. In seven cases referred to by v. Ziemssen, life was prolonged for a period ranging from three to forty-two months after the trachea had been opened. It may also be said in favor of tracheotomy that the operation itself is devoid of danger, and even when it is ineffectual in prolonging life, it gives some relief to the patient's sufferings and promotes euthanasia.

The alternative to tracheotomy, laryngectomy, was shown to be practicable, in experiments on animals, by Czerny, though the first successful operation of total removal of the larynx for carcinoma was performed by Billroth in 1873. Watson, of Edinburgh, is said to have performed laryngectomy in 1866, but his patient died. Billroth's patient lived for a year, and was enabled to talk by means of an artificial larynx. Since that time the number of cases of total extirpation of the larynx has mounted up into the hundreds, though unfortunately not all have resulted as happily as did Billroth's first case. The latest statistics of extirpation of the larynx are those of Hahn, referred to in the *Annals of Surgery* for January, 1886; of Roswell Park, in the "Reference Handbook of the Medical Sciences;" and of Salomon, in his "Tesi di Pavia," 1886. In Hahn's table seventy-two of the ninety-one cases of extirpation reported were for carcinoma, seven of these being partial operations. Of these, twenty-five died within two weeks after the operation. Thirteen of the cases were reported as cured, no return of the disease having occurred up to the time of the report. Park finds the recoveries to be about thirty per cent., though these figures embrace operations performed for benign as well as malignant disease. Salomon has collected eighty-seven cases of laryngectomy for cancer, and of these forty-nine, or 56.4 per cent. survived the operation a sufficient length of time to be reported as cured. The best results, as regards prolongation of life, were obtained in intrinsic cancer. In these cases, the shortest duration of life, in those who survived the immediate effects of the operation, was one year, in the longest eight years, and the average five years. Many of the patients are still alive and entirely free from any cancerous affection. In comparing these results, however, it must be remembered that the operation itself is very frequently fatal, thirty-nine of these eighty-seven having died from its immediate effects. Partial laryngectomy, when the disease is sufficiently limited to render it feasible, gives much better results, as regards the immediate effects, though the statistics are not yet large enough to permit anything definite to be said concerning the ultimate results.

This, therefore, is the alternative which the Crown Prince and his medical advisers have to face: Tracheotomy, with no immediate danger of death, in order to obtain a possible prolongation of life, without voice and without hope, for three or four years; or laryngectomy, with a nearly even chance of immediate death, performed in the hope of an extension of life, possibly to its natural limits; but with an artificial voice and under the constant dread of a return of the malignant growth, either in the cicatrix or in some other organ of the body.

THE EARLY HISTORY OF VACCINATION IN AMERICA.

If those good people who waste their breath and make themselves more or less ridiculous by declaiming against one of the grandest discoveries of medical science would study with a little seriousness the history of vaccination, they might possibly be led to look upon it as less of a curse than they now affect to regard it. At the beginning of this century there was no greater scourge to the human race than small-pox, and even now, such is the traditional fear of the disease, small communities are often plunged into a panic by the occurrence of a single case in the midst of them. But in the larger cities the discovery of a case of small-pox occasions little fear, and its occurrence is chronicled in the papers merely as a piece of news. During the week ending October 29th, in the entire city of New York, with over a million of inhabitants, there were but two cases of this disease reported. That this happy immunity is due chiefly to the protection afforded by vaccination no reasonable man can for a moment doubt.

Eighty years ago the only protection against small-pox was to have had the disease, and our grandfathers and grandmothers were wont to betake themselves to one of the numerous private small-pox hospitals, situated in some isolated country-district, and there be inoculated. They suffered from the disease in a mild form usually, but it was genuine small-pox that they had, with all its dangers and sufferings.

It was at the very commencement of this century, in July, 1800, that Dr. Waterhouse, of Boston, performed the first vaccination in this country, on one of his children. But although Dr. Waterhouse was the first to perform the operation, a large share of credit in popularizing the procedure belongs justly to Dr. Elisha North, of Connecticut. In a very interesting sketch of the life of this really great physician, read before the New London County Medical Association, in April, 1887,[1] we find many details of his early experiments with vaccination. His first experiment was made in the fall of 1800. The virus was obtained from the arm of a man who had been vaccinated seven days previously. Two children and one adult were the subjects of this experiment, which was successful in the case of the two children, but failed to take in the person of the adult. This success induced Dr. Carrington, another physician of the same town, Goshen, to undertake vaccination, and for some time these two worked along in a spirit of friendly rivalry, acquiring much valuable experience, at the expense, sometimes, of their patients, and gaining knowledge which was to be of use to all future generations.

It is interesting to learn that the first successful vaccination in New York was performed with virus taken from a patient of Dr. North. The operation was performed by Dr. Edward Miller, one of the editors of the *Medical Repository*. The virus used was but the third remove from the cow. It was taken from a Mr. Hunt, who had been vaccinated from the arm of a girl, and the virus for her vaccination had been taken from a cow-pox pustule on the hand of a Mr. Ives. This man Ives had applied to Dr. North, complaining of headache, chills, and fever, a swelling in the axilla, and a sore on the hand. The sore was found to be a cow-pox pustule, and inquiry showed that it had been acquired by direct infection from the udder of a cow, while milking. Dr. North pursued his inquiries still further, the result of which, he wrote, "amounted to this, that the cow did not get her disease from the human subject nor from the horse." This remark would seem to show that Dr. North recognized the identity of small-pox and cow-pox, a fact which was proved experimentally, forty years later, by Dr. Ceeley, of England.

Dr. North subsequently removed to New London, where many now living remember him as a most accomplished, though eccentric, physician. But few, we imagine, remembered or knew the great services that he had rendered humanity by his labors in promoting, despite popular opposition and professional prejudice, the general adoption of vaccination. Dr. Bolton has rendered a genuine service to the history of medicine in America in collecting these facts in his sketch of the life of his illustrious ancestor.

[1] Life and Writings of Elisha North, M.D., by his grandson, H. Carrington Bolton, Ph.D.

WASHING OUT THE BODY IN CASES OF POISONING.

It is a well-known fact that the blood possesses the property, under normal conditions, of maintaining itself at a constant density and volume, and is able to correct with considerable rapidity any slight changes, on one side or the other, from the normal, from whatever cause arising. Thus, after a hemorrhage, unless it be excessive in amount, water is absorbed from the tissues, and new red corpuscles are formed with such rapidity that a very short time suffices for a complete restoration of the blood to its normal density and volume. In the same way, the ingestion of large quantities of fluid increases the volume of the blood only temporarily, the excess being rapidly eliminated by the proper emunctories.

A consideration of these facts has led Dr. Carlo Sanquirico, of Sienna, to undertake a series of experiments to determine whether it be not possible to promote the elimination of poisons by increasing the activity of secretion by means of intravenous injections. These experiments differed from those which Landerer was making about the same time in Germany. The latter endeavored to abstract the poison directly from the blood by venesection, supplying the loss of fluid by the injection of an equal amount of a saline solution. Sanquirico did not abstract any blood, except in a few of his experiments, but injected a quantity of a saline solution, with the object of increasing the volume of the blood, and so promoting the elimination of the poison through the kidneys.

The results of these experiments are published in the *Archivio per le Scienze Mediche*, vol. ix., No. 3. Dogs and guinea-pigs were used, preliminary experiments being made to determine the fatal dose, for each, of the poisons administered. The amount of the saline solution injected was in the proportion of eight per cent. of the weight of the animal. The experiments were successful, the results being sometimes really astonishing, after poisoning by strychnine, chloral, alcohol, aconitine, paraldehyde, caffeine, and urethan. But, on the other hand, all the animals to which morphine, curarine, nitro-

benzol, hypnone, or nicotine had been given, died, in spite of the saline transfusions. In these cases of non-success there was no increased urinary excretion, while in the cases in which the lives of the animals were saved the flow of urine was almost continuous.

These experiments, which are reported in detail in the journal above mentioned, were very interesting in their results, and give promise of being turned to a useful purpose in the treatment of acute poisoning in the human subject. In strychnine poisoning especially, if further experiments bear out the conclusions of the author, this method of washing out the body may not improbably prove to be a most precious means of saving life in otherwise hopeless cases.

THE GLEDITSCHINE INQUIRY.

THERE is so much interest manifested in the authenticity of gleditschine as a veritable alkaloid that THE MEDICAL RECORD has determined, in accordance with its previous promise, to make suitable investigations regarding the question. We have deemed it best for all parties concerned in this inquiry that the leaves of the "tear-blanket" tree shall be expressed to us directly by an impartial party, and shall be examined by Dr. Charles Rice, of this city, who will report the result in due time.

Drs. Goodman and Seward will be invited to give such information to the analyst as may aid him in his investigations, but any chemical processes which may be either novel or necessary to procure the product shall be fully published, as is proper with any other scientific intelligence.

We have already ordered the leaves from a responsible party in New Orleans, and shall expect them to arrive in proper condition. At the earliest possible moment we shall publish the results of the analysis.

WHAT THE FRENCH THINK OF THE NEXT INTERNATIONAL CONGRESS, TO BE HELD AT BERLIN.

THE *Journal de Médecine de Paris*, of September 25, 1887, winds up an editorial notice of the recent Washington meeting of the International Medical Congress with the following ridiculous tirade:

"Through the influence of Professor A. Martin, Berlin was selected as the place of meeting for the next Congress. Under the circumstances governing this selection, and in view of the relations existing between America and France, we consider this choice a positive insult to our country (*une véritable insulte pour notre pays*).

"The American physicians have bent under the Prussian yoke; we announce this fact, and shall remember it. Certain it is that the next meeting will not be an *International Congress*, but merely a German reunion."

It is not our province to either settle or foment international quarrels of such moment as the present one appears to be. Still, we take this occasion to inform our much-ruffled Gallic contemporary that American physicians have neither seen nor even heard mentioned that "Prussian yoke" which has so successfully upset his usually calm temperament and generally benign disposition.

Attendance upon International Medical Congresses has been and will continue to be purely voluntary, for individuals as well as for nationalities.

If the efforts of Dr. Le Fort, who proposed Paris as the next place of meeting, had been successful, we doubt whether any reputable German medical journal would have published a remonstrance so violent, contemptuous, and uncalled for as the one from which we have quoted. If these periodical gatherings cannot take place without stirring up local contentions, or giving rise to international complications, they had better be discontinued altogether.

GLOBUS HYSTERICUS.

THIS symptom is one of the most characteristic ones of that state known as hysteria. It has generally been regarded as a localized spasm of the muscular fibres of the œsophagus. It involves successively different segments of this tube, and so gives the sensation to the patient of a ball rising in the throat. But as our knowledge of this condition has become more definite it has been found erroneous to regard it merely as an hysterical manifestation. Some ten years ago, Mr. Lennox Browne, of London, began to seek for it an objective explanation. He communicated his opinion to the Congress of throat specialists in Milan, in 1880, and has, during his recent visit to the Washington meeting, taken occasion to read an interesting paper on the subject before one of the Philadelphia Societies.

He finds that few cases of globus hystericus are of an hysterical character—that is, of the nature of a phantom sensation—though uterine or ovarian disorder predisposes to or accompanies the affection. "Extending the term 'globus hystericus,'" he says, "I find that, with hardly an exception, all and every other subjective sensation in the throat is symptomatic of an objective cause. The chief of such feelings are those of a heat, a prickling, a swelling, a weight—a straw, a hair, or other foreign body. A few patients have complained of an intense cold, which is sometimes relieved, sometimes aggravated, after food-taking. In some instances there is actual pain with spasm, cramp, and a sensation of choking, and not infrequently there is cough; this symptom varies in degree from a slight hacking to the loud, hyena-like bark known as nervous laryngeal cough."

Examination of throats with this train of symptoms has revealed, in his experience, chronic congestion with relaxed uvula and fauces, tonsilar enlargement or crypt obstruction, with cheesy material, and in some cases a true hyperæmia of the laryngeal mucous membrane. With the laryngoscope, the base of the dorsum of the tongue, and sometimes the under surface and sides, are seen to be the seat of a varicositis, and even hemorrhoidal conditions of the veins. This latter change may be an expression of mitral insufficiency or of hepatic derangement, rarely of cerebral trouble. The vessels of the superior surface of the glottis are frequently similarly affected.

In other cases, close inspection has shown an enlargement of the circumvallate papillæ on the back of the tongue, causing an interference with the free movements of the epiglottis. In a few instances the orifices of the glands are occluded, as is the case in chronic follicular tonsillitis.

Mr. Lennox Browne makes the practical remark that, in order to see this state of affairs, a mere tongue-depressor will not suffice. A throat-mirror must be used, and placed quite high up in the pharyngeal vault. "Many observers," he remarks, "especially beginners, seem to consider that their sole aim is to see the vocal chords; and if these are sound, they write down 'larynx normal,' but omit to look well to the framework."

Besides these internal states, he often finds a fulness of the thyroid isthmus, without any enlargement of the lateral lobes. A varicose diathesis—as expressed in varicocele, varicose veins, etc., is often present—with a generally defective circulation and constipation.

The whole paper is a plea for the careful examination of the throats of all patients complaining of globus hystericus. We should search for the objective organic cause, and not dismiss the case with the superficial diagnosis of hysteria. Of remedies in the above circumstances, Mr. Lennox Browne gives chalybeates and aperients with digitalis and ergot. For local use chloride of iron or sulphate of zinc seem to form in solution the best astringents. Gargles are generally useless. They do not often get to the seat of the trouble. Resolution of venous congestion is best promoted by muriate of ammonia tablets.

News of the Week.

The Cancerous Growth in the Crown Prince's Throat is situated just below the left vocal chord. A slight growth is said to be beginning on the right side. This, if true, excludes the operation of partial laryngectomy. As the prince refuses—wisely, we think—to permit the operation of total extirpation, the only remaining surgical measure is tracheotomy. This may prolong his life for a year or two.

Dr. Moses Gunn, who died in Chicago on November 4th, has long been known as a brilliant surgeon and teacher. He was born in this State, in 1822, and graduated at the Geneva Medical College. He taught at Ann Arbor for fifteen years, was surgeon in the army during the war, and had been for the last twenty years the popular Professor of Surgery at Rush Medical College.

Dr. Adam C. Hoffman, of Jersey City, died at Portland, Me., on November 14th.

Dr. William H. Peer, of Brooklyn, died on November 14th. He was sixty-six years of age, and for thirty-six years had practised medicine in the Eastern District, building up in that time a large fortune. He was graduated from the New York Medical University in 1851.

Dr. William O'Gorman, aged sixty-three, died on November 10th, at Newark, after a long illness. He was born in Dublin, and came to the United States in 1849, and in 1857 began practice in Newark. He had been President of the State Medical Society, and the Essex County Medical Society, and was Chief of the New Jersey Medical Staff during the war.

Dr. Sheldon C. Johnson, a prominent physician of Seymour, Conn., died on November 13th, aged ninety. He had been in practice for over half a century.

Virchow and Pachydermia Verrucosa.—In view of the unhappy issue in the case of the Crown Prince, one is inclined to ask what Professor Virchow meant by his learned disquisition on the peculiar warty growth which he called pachydermia verrucosa, and which he appeared to think existed in a benign form in the prince's throat. Was he deceiving himself, or was he mistaken, or has the prince got a benign warty growth developed into an epithelioma?

A Post Graduate Medical School is to be organized at Atlanta, Ga.

Mr. Gladstone ascribes his splendid health and longevity to having learned one simple physiological lesson, viz., to make twenty-five bites at every bit of meat.

Dr. P. Brynberg Porter has retired from the editorship of Gaillard's *Medical Journal*, which he has conducted so ably. His successors are Dr. George Tucker Harrison and Dr. J. H. Claiborne, Jr.

Dr. Frederick Hyde, of Cortland, N. Y., died at his home in that place on October 15th, aged eighty. He was at one time President of the New York State Medical Society, and was one of the organizers of the American Medical Association.

Another Office Thief.—A tall, dark complexioned, shabbily dressed man is now calling on physicians with forged notes from brother physicians asking the loan of a hypodermic syringe for a fictitious emergency case in the neighborhood. He is a thief, and must have quite a collection of instruments by this time.

M. Pasteur's health is said to be still in an unsatisfactory condition, so much so as to necessitate confinement to his house.

Dr. Bernard Kraus, chief editor of the *Allgemeinen Wiener Medizinischen Zeitung*, died on the 28th ult., aged fifty-nine.

Sir William Gull is said to be recovering from his attack of hemiplegia.

The Sterility of Tumors and of Healthy Tissues.—The report of the Scientific Grants Committee of the British Medical Association, made by Messrs. C. A. Ballance and S. G. Shattuck, on cultivation-experiments with malignant new-growths and with healthy tissues has been made. Careful experiments showed what has been shown before, that there is no parasite in cancer or sarcoma that can be cultivated by known methods. It was also shown that healthy living tissue contains no micro-organisms and is sterile.

An Unfortunate Incident has occurred at the General Hospital, Vienna, which has ended in the dismissal, by ministerial decree, of Dr. Lustgarten from the post of assistant to the Professor of Dermatology, Dr. M. Kaposi. It appears that through a misunderstanding Dr. Lustgarten thought that the director of the hospital had sent him an insulting message. He in return wrote an offensive letter to the director, and was dismissed in consequence.

Dr. John C. Peters will read a paper before the Section of Hygiene of the Academy of Medicine, on December 2d, "On the Laws for the Prevention of those Things which Cause Discomfort and Disease."

Reports of Societies.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Fifteenth Annual Meeting, held in Memphis, Tenn., November 8, 9, 10, and 11, 1887.

(Special Report for THE MEDICAL RECORD.)

TUESDAY, NOVEMBER 8TH—FIRST DAY—MORNING SESSION.

THE first session was called to order at ten o'clock on Tuesday morning, in the room of the United States Court, by MAJOR GEORGE M. STERNBERG, M.D., U.S.A., President.

After some announcements by the Chairman of the Local Committee and the election of ninety-four new members, the reading of the treasurer's report was taken up. It showed a balance of $920.65 on hand. Then followed the reading of papers.

THE ORIGIN OF SOME DISEASES

was the title of a paper by DR. EZRA M. HUNT, of Trenton, N. J., Secretary of the State Board of Health. He stated that in considering the nature of disease two great principles should be borne in mind: (1) The changes brought about in the processes of evolution, and the fixedness of type that may be acquired; and (2) the results of hybridization as seen in disease. He gave facts as to the fertility of hybrids and their tendencies to become specialized. He quoted several authorities as showing that the general views of the profession did not accord with botanists. While he admitted that diseases generally come from antecedent cases, he claimed that they sometimes originate, or change in type, under special influences in persons and surroundings.

DR. HUNT then read a second paper upon

THE PREVENTION OF MICROPHYTIC DISEASES BY INDIVIDUAL PROPHYLAXIS.

(This paper will appear in full in our next issue.)

These papers gave rise to an interesting discussion, in which several health authorities participated, some of them fearing that the preaching of a doctrine that disease could be prevented by medication would nullify all efforts at real sanitary advancement.

Papers were then read by DR. CARL HORSCH, of Dover, N. H., on

THE NECESSITY OF BURIAL PERMITS AND INSPECTION OF BODIES OF DECEASED PERSONS,

recommending the establishment of houses similar to those in Germany for the reception and care of dead bodies, for inspection before burial.

A paper was then read, prepared by DR. JOHN S. BILLINGS, U.S.A., on

SOME FORMS OF TABLES OF VITAL STATISTICS, WITH SPECIAL REFERENCE TO THE NEEDS OF THE HEALTH OFFICER.

It was accompanied by numerous blank forms, and described the method of compiling vital or other statistics by the use of punched cards and an electrical machine.

DISINFECTANTS.

DR. GEORGE H. ROHE, of Baltimore, read an abstract of the work of the Committee on Disinfectants, of which Dr. Sternberg was chairman during the year. The following conclusions are drawn from the abstract:

1. The temperature required to destroy the vitality of pathogenic organisms varies with the different organisms.

2. In the absence of spores the limits of variation are about 10° Centigrade (18° F.).

3. A temperature of 56° C. (132.8° F.) is fatal to the bacillus of anthrax, the bacillus of typhoid fever, the bacillus of glanders, the spirillum of Asiatic cholera, the erysipelas coccus, the virus of vaccinia, of rinderpest, of sheep-pox, and probably of several other infectious diseases.

4. A temperature of 62° C. (143.6° F.) is fatal to all of the pathogenic and non-pathogenic organisms tested, in the absence of spores (with the single exception of *sarcina lutea*, which in one experiment grew after exposure to this temperature).

5. A temperature of 100° C. (212° F.), maintained for five minutes, destroys the spores of all pathogenic organisms which have been tested.

6. It is probable that some of the bacilli which are destroyed by a temperature of 60° C. form endogenous spores which are also destroyed at this temperature.

EVENING SESSION.

At the evening session HON. J. W. CLAPP delivered an address of welcome for the city, and GOVERNOR ROBERT L. TAYLOR for the State. PRESIDENT STERNBERG then delivered his address, of which the following is an abstract:

PRESIDENT'S ANNUAL ADDRESS.

MAJOR STERNBERG began his address by referring to the special interest felt in Memphis by the Association, because in her hour of distress she appealed to some of our most distinguished members for sanitary council and acted upon the advice given. The organization of a National Board of Health and its unhappy failure were referred to, and it was stated that, to be efficient, any new central health board must be attached to some existing government department, so that it may be under the protection of a cabinet officer; suggesting a bureau of public health with a commissioner at its head, with a bacteriological laboratory attached to it. In connection with the bureau of public health, the President suggested an "advisory board of health," consisting of the surgeons general of the army, the navy, and the marine hospital service, and of the presidents of the State boards of health. He recommended that this plan should be brought before Congress. Speaking of yellow fever, he stated that recent epidemics had shown that our coasts were quite as favorable for the prevalence of yellow fever as in former years, and urged great care in recognizing early cases of yellow fever in unexpected localities. He then described the plan of quarantine by supervision, detention, and disinfection, as recommended by the International Quarantine Commission, of which he was a member. Concerning cholera at New York, he said that it was, perhaps, too soon to speak with confidence with reference to the action taken by the sanitary officials of the port of New York upon the recent arrival of two cholera-infected vessels from the Mediterranean, but he had good reason to hope that the measures taken will prove sufficient, and that this pestilential disease, which has for several years been threatening us from a distance, has not effected a lodgement upon our shores.

Whether it would be practicable to put our seaports in such a state of sanitary defence that it would be safe to open the door and defy the foe is extremely doubtful, but he did believe that cities could be preserved from epidemics by carrying out needed sanitary improvements, and the constant supervision of expert sanitary officials, supported by an enlightened public sentiment and sufficient appropriations. Cholera was even easier controlled than yellow fever, as it depends largely, if not exclusively, upon the water-supply for its epidemic extension. The taxing of commerce for the support of quarantine establishments he considered wrong in principle, and unjust to those who have to bear the burden. Those protected should pay the cost of such protection, and quarantine establishments should be supported at the expense of the National Government or of the States

in which they are located. The farcical method of disinfecting a ship upon which he came into the port of New York was described, the operation being gone through in a ridiculously inefficient manner, apparently for the sole purpose of securing a fee for disinfecting the ship. He recommended the adoption of uniform quarantine regulations at all our seaport towns. Having spoken of the exotic pestilential diseases as they afflict our country from time to time, he recommended that we study more carefully such epidemic diseases as typhoid fever, scarlet fever, small-pox, etc., and apply vigorously the rules we were cognizant of for their banishment. The importance of teaching personal hygiene was spoken of, and the granting of prizes for sanitary essays suggested. The investigation of special fields in sanitary work by expert scientists offered a rich field for the Association to work in, and he acknowledged the good done by the various bacteriological laboratories already in operation, referring particularly to the discovery of tyrotoxicon by Dr. Vaughan. For encouraging scientific investigation of sanitary problems, he suggested that the Association raise a special fund for this purpose by contributions.

Fit subjects for investigation were the biological investigation of water supply of towns and cities, and the possibility of protecting individuals from the infectious diseases by inoculations with an attenuated virus. In speaking of the various diseases which could be restrained by inoculation, he ventured the hope that, in all diseases in which a single attack protects from future attacks, protective inoculations may be practised when once we have succeeded in isolating and cultivating outside the body the specific infectious agent. Four methods of attenuating the potency of disease-germs were mentioned: Exposure to heat, exposure to oxygen, exposure to certain chemical agents (discovered by himself in 1881), and by passing through the body of certain animals. Among the diseases which it is hoped could be controlled, could one succeed in isolating and cultivating the specific germ, is yellow fever; and he regretted that his orders, not to make publication of his findings in his special mission to investigate the claims of Freire and Valle until he should have made a final report to the President of the United States, made it impossible for him to speak on those claims. He spoke of the great activity in bacteriological research, and said that recent investigations give support to the conclusions of Koch as to the pathogenic rôle in cholera of the spirillum discovered by him in the intestine of cholera-patients.

The work of the Committee on Disinfectants was spoken of, and its results are referred to in another place. The question of the etiological rôle and biological character of the typhoid bacillus of Eberth was touched upon, and the important additions to our knowledge of this organism were noted, and its growth in drinking-water particularly referred to. The etiology of croupous pneumonia was referred to as having caused much discussion during the year, and it was stated as being now evident that the bacillus of Friedländer, called "pneumococcus," is not entitled to this distinctive appellation. But evidence is accumulating that a micrococcus which he had named *M. Pasteuri*, and which is found in normal human saliva, is far more frequently found in the exudate into the alveoli, during the acute stage of croupous pneumonia, than is that of Friedländer. It was in January, 1885, that he first discovered this in pneumonic sputum and made inoculations in rabbits with it. After summing up the opinions of others concerning the action of this bacillus, he speaks of the importance of secondary causes which control the endemic and epidemic prevalence of pneumonia, which have been satisfactorily worked out by Dr. Baker, of Michigan. The important investigations of Councilman, of Baltimore, and Osler, of Philadelphia, with reference to the presence of micro-organisms in the blood of malarial fever patients, were commented on as confirming the discovery of Laveran in 1880, that during a febrile paroxysm the blood contains parasitic infusoria. He reiterated his opinion that the bacillus malariæ of Klebs and Tomassi-Crudeli did not, when injected under the skin of a rabbit, give rise to a malarial fever corresponding to the ordinary paludal fevers to which man is subject. Brief references to deceased members completed the address.

WEDNESDAY, NOVEMBER 9TH—SECOND DAY—MORNING SESSION.

The Committee on State Boards of Health asked for a portion of Thursday to be set apart for discussing these points: 1. Views of members of State and Provincial health boards as to whether State systems of quarantine should be replaced by a national system. 2. What are the privileges and expediencies of State officers as to the investigation of epidemics at threatening points? 3. Inter-State notification of diseases.

A resolution was adopted appointing a committee, of which Dr. Sternberg should be chairman, to study experimentally the methods and effects of protective inoculation against infectious diseases.

A resolution was offered by DR. OTTERSON, of Brooklyn, looking toward congressional action for appropriations for Government quarantine stations.

FOOD INSPECTION AND SUPPLY.

DR. HORSCH, of Dover, N. H., sent a paper on "Inspection of Animals required for Food," recommending their inspection by competent persons before slaughtering, and examination of internal organs afterward.

The paper by DR. AZEL AMES, JR., of Chicago, upon the "Meat-food Supply of the Nation and its Future," was a statistical and authoritative review of the status of the animal-food resources of the country. It put in strong light the steady proportionate decline of our flesh-food production to our rapid doubling of population, and the constant reduction of the grazing area. Disease and unwise laws and administration were shown to be grave abnormal influences, limiting and depressing the production of food-animals and their products. The paper, in a clear but temperate way, condemned the course of the Administration for its public-land policy, and appealed strongly for right and the interest of all in the regulation of oleomargarine and similar food-products. It invoked action in behalf of legislation by Congress for the suppression of pleuro-pneumonia, a thorough enumeration of cattle and their products in the Census of 1890, and the repeal of the special tax upon retailers and wholesalers under the Oleomargarine Act as unjust to the poor, wrong in principle, and repressing to the food-supply.

CHOLERA AND QUARANTINE

was the subject of a paper by DR. JOHN H. RAUCH, of the Illinois State Board of Health. It described the deficiencies in the New York quarantine, speaking of the distrust with which its results were looked upon in the West, and asked for national control of the quarantine system of the country.

The discussion elicited from DR. MONTIZAMBERT, Dominion quarantine officer for Canada at Grosse Isle, the statement that their regulations were more stringent than ever.

DR. A. N. BELL, of Brooklyn, then gave a detailed history of the condition of affairs at New York quarantine, in which the arrangements were characterized as infamous in their inefficiency, but nevertheless expressing the belief that the work done on the Alesia's and Britannia's passengers was successful, and that no cases of disease would be caused by landing them.

DR. WILLIAM OLDRIGHT, of Toronto, Ont., introduced a resolution looking to the abolishment of the present system of scattering excreta along railway tracks by passenger trains.

Dr. C. N. Hewitt, of Red Wing, Minn., said the only way we could bring New York quarantine into condition was to touch them through a harassed commerce with Western States.

Evening Session.

The first paper was on

THE MALARIAL GERM OF LAVERAN,

by Dr. William T. Councilman, of Baltimore. In brief, he said that this organism most probably belongs to the protozoa, a group of unicellular organisms noted for the varied changes of form which the individual examples undergo in the course of development. The malarial organism forms no exception to this. Ten more or less distinct forms are seen. Of these five, in which the connection can plainly be made out, are always found in intermittent fever. Other forms are found in malarial cachexia. It is interesting to note that a definite form, in which multiplication of the organism by segmentation takes place, is found in the period of chill, and at no other time.

Some forms of the parasite are common to all forms of malarial infection. The form which is provided with actively moving filaments is found but rarely in the blood drawn from the finger, but may be found in cases either of an acute or a chronic character. In the examination of blood taken directly from the spleen, it was found in ten out of twelve cases of malarial cachexia, and in five out of eight cases of intermittent. Too much importance cannot be assigned to this organism as a means of making a differential diagnosis between malarial fever and typhoid fever simulating this. It is in outbreaks of fever in small country-towns, where it is of the greatest importance that the character of the disease should be recognized promptly, that the advantage of this mode of diagnosis is most evident. There is too much reason for believing that, in localities where the various forms of malarial infection are more common, epidemics of typhoid fever in which the fever follows a more or less typical course, and where autopsies are not to be had, are mistaken for malarial fever.

LOUISIANA QUARANTINE

was treated of by Dr. Joseph Holt, of New Orleans, who gave the reasons which led them to depart from the time-honored ideas of quarantine detention to preserve their commerce.

Thursday, November 10th—Third Day—Morning Session.

Thirty-three new members were elected. Resolutions offered the day before were adopted.

MORE PRIZE ESSAYS.

A telegraphic despatch from Mr. H. Lomb, of Rochester, was read, offering prizes of $500 and $200 for best essays on "Practical Sanitary and Economic Cooking adapted for Persons of Moderate and Small Means." The offer was accepted.

A resolution was offered by Dr. J. N. McCormack, of Bowling Green, Ky., urging the

NEW YORK QUARANTINE

authorities to revise and modernize their methods.

Dr. Bell, of New York, moved that a committee of three be appointed to report upon such sanitary and medical service on board emigrant vessels as may be secured by congressional action.

They were both referred.

Dr. La Berge, Medical Health Officer of Montreal, described their system of collecting garbage and burning it by the Mann furnace. Other forms of furnaces were described.

QUARANTINE

formed the subject of another discussion precipitated by the Committee on State Boards of Health. Dr. Walter Wyman, U.S.M.H.S., Dr. Joseph Holt, Dr. Bell, Dr. La Chappelle, of Quebec, Dr. L. F. Salomon, New Orleans, and Dr. H. B. Horlbeek, Charleston, took part in it. The balance of sentiment was plainly in favor of State quarantine aided by the National Government when needed.

Evening Session.

Vice-President C. N. Hewitt called the meeting to order, and a paper on

RIVER POLLUTION,

prepared by Prof. S. W. Williston, of New Haven, Conn., was read. It detailed the amounts of chemical pollution poured into several Connecticut streams, and stated that such pollution was not infective in its character.

In the discussion, the only prominent point made was by Rudolph Hering, C. E., of Chicago, who stated that the amount of pollution of streams, not to be used for water-supply, which was permissible before advising the disposal of sewage by land-filtration or chemical treatment, was limited to the sewage of one thousand persons to each 120 to 150 cubic feet of minimum river-flow per minute in summer, and to 180 to 240 cubic feet in winter, when the river should be covered with ice.

Friday, November 11th—Fourth Day—Morning Session.

The last session was consumed in the appointment of committees, election of officers, etc. Resolutions offered by Dr. McCormack, concerning improvements at New York quarantine, were redrawn so as to apply to all ports, and passed.

NEW OFFICERS

were elected, as follows:

President—Dr. Charles N. Hewitt, Red Wing, Minn.

Vice-Presidents—Drs. G. B. Thornton, Memphis, and Joseph Holt, New Orleans.

Executive Committee—Drs. Henry B. Baker, Michigan; S. H. Durgin, Massachusetts, and J. N. McCormack, Kentucky.

The Secretary, Irving A. Watson, M.D., of Concord, N. H., holds over.

Milwaukee was decided upon as the place of meeting next year.

Six new members were elected.

COMMITTEES

were appointed on State boards of health, on pollution of water-supply, on disposal of garbage, on animal diseases and animal food, on forms of statistics, on incorporation, on protective inoculation experiments, on Lomb prize essays, on national health legislation as recommended by President Sternberg, and on improvement of the sanitary and medical service on emigrant ships.

After resolutions of thanks, the Association adjourned *sine die*.

Antipyrin in Uterine Colic.—Dr. Chouppé has published two cases of uterine colic successfully treated with antipyrin injections. The first was in the case of a woman who suffered at each menstrual period with very painful colic, which was with difficulty overcome by opium and chloral. Antipyrin, in the dose of fifteen grains, gave rapid relief. The second was the case of a woman suffering from uterine colic after childbirth. The pains were subdued for five hours by a first injection, and disappeared completely under the influence of a second.—*Semaine Médicale.*

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, October 27, 1887.

ALEXANDER S. HUNTER, M.D., CHAIRMAN *pro tem.*

ASPHYXIA NEONATORUM.

DR. J. LEWIS SMITH read a paper on the above subject, in which he stated that the term was applied to the state of the infant when it exhibited no signs of animation after birth, but was still living.

It occurred more frequently with primiparæ than multiparæ, and with male than female infants.

There were two varieties, the *asphyxia lividum* and the *asphyxia pallidum.*

The asphyxia lividum, or apoplectic form, was characterized by muscular tonicity—the head, limbs, and lower jaw did not drop when the child was raised. The cutaneous, and, to a certain extent, the mucous surfaces, had a dusky color; there was general venous congestion; the lips and tongue sometimes swollen, etc.

The asphyxia pallidum was characterized by general lack of muscular tonicity—the head, the limbs, and the lower jaw dropped; the eyes were glassy, the pupils more or less dilated; the color of the surface pale; the general appearance markedly anæmic, etc.

Asphyxia lividum became asphyxia pallidum before death took place.

ETIOLOGY.

The causes were divided into two groups—first, intrauterine; and second, those which affected the child during its birth or immediately afterward.

In the first group was placed any cause which interrupted central circulation or rendered it inadequate, such as blows or falls which detached a portion of the placenta; grave internal diseases, as of the heart or lungs; profound anæmia; degenerative changes of the placenta; torsion, or knotting, of the umbilical cord; obstruction of the air-passages of the child, etc.

In the second group were placed protracted labor, with strong and frequent uterine contractions, rigid soft parts, and deformed pelvis. A common cause was *the use of ergot.* The immediate cause of death after the use of ergot was intracranial extravasation of blood, especially at the base of the brain.

Prolapse of the cord, breech and transverse presentations, were assigned to this group.

PROGNOSIS.

That depended upon the cause and degree of the asphyxia. If the case was one of asphyxia pallidum, without muscular tonicity, and if the mother had not noticed fœtal movements for a considerable time before the termination of labor, the prospect of resuscitation was not good. By active and energetic perseverance he had succeeded in resuscitating the child ten minutes after he was unable to detect any heart-beat, either by the ear or the fingers. Certainly there was hope of resuscitating the child as long as the heart beat. But if the pupils remained dilated, it was altogether probable that attempts to produce resuscitation would be wasted. Doubtless a few recoveries had occurred after intracranial extravasation of blood had taken place.

Several reported cases were referred to, in which resuscitation was accomplished after the lapse of from one to five hours; but all those children died within a few days.

If the surface presented a pallid, macerated appearance, and there was absence of muscular tonicity, while there was no respiration, nor appreciable cardiac movement, the child was dead. If there was muscular tonicity and lividity, although there was no appreciable cardiac movement, life was probably not extinct.

TREATMENT.

Remove any obstruction to the entrance of air. Clear the mouth and fauces of mucus. Apply brisk friction up and down the spine, especially in the cervical region. Dash small quantities of cold water upon the face. Plunge the child to the neck into hot (103° to 105° F.) and cold water alternatively; hot water alone was sometimes very effectual. Mouth-to-mouth insufflation. Artificial respiration, which was best accomplished by insufflation.

His method of practising insufflation was to remove all mucus from the mouth and fauces; place the child upon its side upon a table, supported by one hand over the abdomen, with the thumb upon the epigastrium, so as to depress it and prevent the entrance of air into the stomach. Several pieces of muslin, with an oval opening in each, are prepared, to be placed over the mouth of the child, for purposes of cleanliness. Place the mouth firmly against that of the infant, and insufflate ten or twelve times per minute. He disapproved of the tubes devised for insufflation, and also thought that the objections that had been made to the method were frivolous. Of the movement methods, he preferred Sylvester's and Schultze's.

DR. CHARLES JEWETT had found intracranial hemorrhage in the fatal cases, and had no doubt that it was a frequent cause of death.

There was one point in etiology which had interested him; for example, in forceps cases, where no injurious pressure was made with the instruments, yet the autopsy showed that there was intracranial hemorrhage, and it had seemed to him that the fault might have consisted of a weakness of the vessels themselves. He had not been able to resuscitate where he had been unable to detect cardiac movement. He had practised Sylvester's and Schultze's methods, and insufflation with a tube, but his chief reliance was upon the mouth-to-mouth insufflation. Place the child upon the back, with a folded blanket under the neck, so as to put the head in the position of semi-extension; then closing the nostrils he presses with the other hand over the epigastrium. He had endeavored to insufflate the air from the mouth,

AFTER THE MANNER OF USING THE BLOW-PIPE,

instead of using it from the lungs. Of course, undue force must not be used in practising this method. Suspension of the child by the feet was a method that had some advantages.

DR. GARRISH had attended five thousand cases of obstetrics in private practice, and had frequently met with asphyxia neonatorum after the use of ergot by midwives. He believed that ergot should never be given previous to the birth of the child. His method of management had been to pull the tongue of the child out as far as possible, cleanse the pharynx, and then spurt a mouthful of brandy over the thorax, and the child will gasp. If that did not succeed, he gave the warm bath. He did not tie the cord, but divided it. As soon as respiration began and the blood started a little, he then tied the cord.

DR. W. A. FANNING mentioned a case in which he gave one drachm of ergot; the child was born within fifteen minutes and by a single pain, and yet he was unable to resuscitate it. He had heard the fœtal heart distinctly just before the administration of the ergot. He had not given ergot before the child was born since that time.

DR. FRUITNIGHT had no doubt that ergot was a frequent cause of asphyxia in the practice of midwives. In the livid form he divided the cord and allowed blood to escape before applying the ligature. He had resuscitated the children in the milder cases by blowing sharply upon the epigastrium. Electricity should be used when other means fail, and the method was to place one hand over the region of the phrenic nerve in the neck, and the

other over the stomach, and then pass the current through the body of the operator.

Dr. George T. Jackson then read a paper on

IMPETIGO CONTAGIOSA,

in which he directed special attention to the bullous variety, which was liable to be confused with pemphigus. The use of the term impetigo was most frequently associated with the idea of a pustular disease, whereas it was vesicular at first, and the vesicles might be as large as a split pea, the contents of which dried in a few days, and then formed a crust that had the appearance of being stuck on the surface.

In the rarer form of impetigo there were bullæ sometimes showing slight depression in the centre, and it was this form which was liable to be mistaken for pemphigus. It occurred most frequently upon the trunk, was discrete, superficial, bullæ rarely numerous, and showed a tendency to appear in groups.

Impetigo was comparatively rare. It was contagious, and often occurred in epidemics. It was readily inoculable.

The contagious element had not been ascertained. The disease occurred more frequently in the warm months than in the cold. Children furnished the vast majority of cases. The duration of the disease was usually short. Pemphigus occurred most frequently in adults. The treatment consisted in scrubbing the affected parts with soap and water, and afterward applying carbolized ointment.

Dr. Bulkley had nothing special to add to Dr. Jackson's admirable *résumé* of the subject. If the disease was not checked, it would run on for considerable time. It was purely a local disease, but, at the same time, it might be desirable to give tonics for general purposes. The local application which he had used most frequently was the white-precipitate ointment diluted three or four times with rose ointment, perhaps with the addition of a small quantity of carbolic acid.

Dr. W. L. Carr had recently seen *five* cases in a public institution; three in children, and two in adults who took care of the children. In all these cases there was more or less disturbance of digestion. The treatment which he adopted successfully was to wash the parts with a carbolized solution, 1 to 30, use carbolized ointment and zinc ointment, and, internally, rhubarb and soda.

Dr. Holt was somewhat surprised at Dr. Jackson's statement concerning

THE RARITY OF THE DISEASE,

for he had encountered quite a number of cases in children in dispensary practice. He had cured them with white-precipitate ointment diluted with four parts of zinc ointment. Nearly all the children on whom he had seen the disease required a tonic plan of treatment.

Dr. J. Lewis Smith spoke of the occurrence of twelve or fifteen cases among children in the Foundling Asylum, where they were kept exceedingly clean and were well nourished. The disease appeared upon the upper part of the chest and the neck.

Dr. Jackson thought it quite probable that the disease was seen more frequently by those who had classes of children's diseases, and in institutions, than by dermatologists, and he was glad to learn of that fact. It was the bullous variety to which he wished to direct attention specially.

The Section then adjourned.

The largely-advertised proprietary article, known as Ely's Cream Balm, consists of vaseline, 1 ounce; thymol, 3 grains; carb. bismuth, 15 grains; oil wintergreen, 2 minims. The directions are to dip the little finger into the balm and insert up the nostrils, giving two or three full inhalations.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

INTESTINAL SURGERY—THE DIAGNOSIS AND TREATMENT OF CHRONIC OBSTRUCTION—THE CONDITION AND MANAGEMENT OF THE INTESTINE AFTER ABDOMINAL SECTION—THE SCARLET FEVER EPIDEMIC AND THE COMPULSORY NOTIFICATION OF INFECTIOUS DISEASES—THE COMING MEETING AT THE COLLEGE OF SURGEONS.

London, October 31, 1887.

Intestinal surgery is again to the front. At the last meeting of the Medical Society of London, Mr. Treves read a very suggestive paper on the "Diagnosis and Treatment of Chronic Intestinal Obstruction." Mr. Treves remarked that for diagnostic purposes cases might be classified in four groups: 1, Fecal accumulation; 2, stenosis of colon; 3, stenosis of the small intestine; 4, chronic intussusception. This order represented their relative frequency, fecal accumulation being the most common, and chronic intussusception the least frequent. No form of obstruction was more difficult to diagnose than the latter. Out of 55 cases collected by Rafinesque, no fewer than 27 were the subjects of an incorrect diagnosis. The invagination-tumor had been met with in about fifty per cent. of the cases, but in only thirty-two per cent. of the cases did it reach the rectum. Blood in the motions had been recorded in about half the instances of the chronic form. Vomiting was entirely absent in about half the collected cases. The symptoms caused by stenosis of the small bowel were marked by great variations. The onset was usually gradual. The pain was distinctly intermittent. In most cases it was provoked by food. Vomiting was often provoked by food. Stenosis of the colon was in most cases caused by stricture, and in more than half the cases this was cancerous. The most important point in differential diagnosis was to distinguish between stenosis of the colon and fecal impaction. It was as great a calamity to perform colotomy for the latter condition as to persist in the use of enemata and purgatives in cases of cancer of the bowel. The subjects of chronic constipation were mostly adults, and generally females. The cases causing most trouble to the diagnostician were those in which some temporary mechanical occlusion of the bowel (as by kinking) was effected by the fecal mass, and acute symptoms supervened upon the chronic phenomena. The gradually increasing constipation of fecal accumulation might, unlike that of stenosis, reach an extreme degree before any vigorous attacks of colic or sickness occurred. One symptom was of considerable moment, viz., the extreme foulness of the breath so often met with in fecal accumulation, and almost unknown in the subjects of stricture of the bowel.

As the case advanced the abdomen became distended, but it was rare for coils of hypertrophied bowel to be visible through the parietes. It was especially to be noted that the symptoms of pain and sickness appeared late, and seldom manifested themselves till there was evidence of a distended bowel. The fecal tumor was an important feature, but its characters were protean. Enemata, as a means of diagnosis, were practically useless. Still less useful was the long tube. As to treatment in cases of stenosis of the small intestine the most important measure was diet. Washing out the stomach might give more relief than narcotics in acute attacks of pain. If the case became steadily worse, laparotomy was the only alternative. The treatment of fecal accumulation was mainly medical. Mr. Treves drew attention to one cause of constipation which is often overlooked, viz., the want of a proper proportion of fluid in the intestinal canal. Massage and enemata were the main therapeutic agents in cases of fecal obstruction. When the bowel

began to clear itself, aperients might be employed. Calomel acted admirably (given in doses of from ten to fifteen grains;) it should be followed by some saline aperient. In stenoses of the colon dieting was important, but its beneficial effects were not so self-evident as in narrowing of the small intestine. As the case became worse, aperients ceased to be admissible, and in the majority of cases the question of operation sooner or later arose. Colotomy was the operation usually performed, and it was allowed by most surgeons that lumbar colotomy had decided advantages over the inguinal operation. Colectomy had not found much favor with English surgeons. It was difficult and attended by a high death-rate. It was justifiable if the actual stricture were encountered at the colotomy-wound. The main point in the operative treatment of chronic obstruction was whether colotomy was really the best measure for a particular case. In obscure cases the surgeon might well hesitate before committing himself to so decided an operation. He might open the ascending colon in the loin, and subsequently find that the obstruction was at the ileo-cæcal valve. A left lumbar colotomy might be performed, and the case might prove to be one of fecal impaction. Mr. Treves said he would strongly advise that in all cases of doubt an exploratory incision should be made in the median line. If the examination showed that colotomy was required, that operation could be either carried out at once—and possibly through the median line—or the peritoneal wound might be closed and lumbar colotomy subsequently performed after the median incision had healed. Two cases illustrating these two alternatives were described.

In the discussion which followed the reading of Mr. Treves' paper, Mr. Davies-Colley remarked that he had found difficulty in diagnosing peritonitis and typhlitis from intestinal obstruction. Mr. Jessett preferred inguinal colotomy, while Mr. Pitts defended the lumbar operation. Dr. De Havilland Hall advocated the use of rectal suppositories of beef peptonoids in cases of stricture of the small intestine. Mr. Allingham, Jr., had seen much benefit follow forcible dilatation of the sphincter ani in some cases of fecal accumulation. Mr. Treves, in reply, said that the points he relied on in the diagnosis of peritonitis from obstruction were the presence of ascites, the continuous character of the pain, the posture of the patient, the constant "meaningless" vomiting, early abdominal distention, and the absence of visible coils of bowel.

On the following evening the first ordinary meeting of the Medical and Chirurgical Society was held, and was entirely occupied by a discussion on the condition and management of the intestine after abdominal section. Mr. J. D. Malcolm read a paper on the subject, in which he maintained that the functions of the intestine were under the control of automatic nervous plexuses in its walls, and that these were closely associated with the central nervous systems, but also affected by stimuli acting directly upon them. Stimulation of the motor plexus produced increase of its activity, followed by exhaustion and paralysis of its function. The author showed that in every abdominal section the intestine is abnormally stimulated, and compared the result to the "after-constipation" of purgatives. Evidence was adduced of paralysis of the bowel after these operations, which gradually recovered in from four to six days, and it was observed that the excessive development of intestinal gases which occurred at this time was connected with defective or deranged innervation. The importance of the escape of these gases was dwelt on. The author showed intestinal paresis to be an important factor in the production of obstruction of the bowels in such cases, and a possible sole cause of death with symptoms of obstruction. He believed that excessive or irritating discharges retained in the peritoneal cavity quickly produced symptoms of obstruction and of peritonitis. In the management of these cases, the necessity of having the bowels cleared of all accumulations before operation was insisted on, and the greatest care was advocated in avoiding all unnecessary exposure and handling of the parts during operation. It was of paramount importance to secure immunity from infection of any kind, but the stimulating and chilling effects of carbolic acid and of the spray were mentioned as dangers. After operation, the necessity for intestinal rest was urged, and the use of opium commended.

Mr. Alban Doran did not think that flatulence was necessarily due to the operative interference. Opium might be useful, but often tended to produce depression and dyspepsia, and, further, it undoubtedly favored the formation of scybala. Mr. Knowsley Thornton said the flaccid state of the intestine after operation was of pretty general occurrence, and the causes, he believed, were as indicated by Mr. Malcolm. He thought that in some cases the rapid distention of the intestines produced death by syncope. Mr. Clement Lucas supported Mr. Malcolm's views as to the causation of paralysis of the intestines. Such paralysis was observed after lumbar nephrectomy. He had seen cases of death from simple over-distention of the intestine. Exposure and injury of the bowels and peritonitis were the chief causes of distention of the bowels. Mr. Meredith thought benefit could sometimes be obtained in cases of flatulence by raising the lower part of the patient so as to favor the escape of the flatus by the anus. He had found injections containing tincture of belladonna (twenty drops) to be useful in reducing the flatulence.

The scarlet fever epidemic continues to increase. Urged, doubtless, by this fact, the Metropolitan Asylums Board have just passed a resolution that it is desirable that the Local Government Board should take the necessary steps for extending to the metropolis the system of compulsory notification of infectious diseases.

The Annual Meeting of Fellows and Members of the College of Surgeons will take place in a few days. Efforts are being made by the party of reform to secure a large attendance, and some vigorous speeches are expected. I shall hope to be able to be present and to give some account of the proceedings in my next letter.

MODERN MEDICINE IN CHINA.

To the Editor of The Medical Record.

Sir: While the advances made in medicine and surgery, both in Europe and America, are familiar to us all, we seldom hear of the work that is being done in Asiatic countries. We know that India and Japan are making progress. Until a recent period but little had been accomplished in China. Last year a medical association was formed for all China. It numbers some eighty European and American members, and fifty or more honorary members, who also take a part in its proceedings. Dr. Kerr, of Canton, is President, and five Vice-Presidents, one for each district of China, preside over the district meetings. The association publishes a quarterly journal of its proceedings. There are eighty hospitals and dispensaries, presided over by English or American doctors, scattered throughout China, and a vast number of the natives, of all ranks, apply for and receive relief in these institutions. Some fifty-three works on the various branches of the study of medicine have been translated into the native tongue by the labors of Drs. Hobson, Kerr, Osgood, Dudgeon, and others. Doctors have had native pupils study with them, with more or less good results. The time has at length arrived when the English language is eagerly studied by the native Chinese. Some Chinese medical students are now pursuing their studies in English, and there is an opening for the more complete and thorough education of native medical men in our modern medical science. There are many reasons why Shanghai should become the medical centre for all China. It is the commercial metropolis of China. All the great foreign lines of steamers from Europe,

America, and other points terminate there; men from all the provinces of China are continually visiting Shanghai. Some three to four thousand Europeans and Americans reside there; fifteen English, French, German, and American doctors live in Shanghai, and as the most money can be made there, the best medical talent gravitates to that centre. Four hospitals for Chinese, with about two hundred and fifty beds, and an out-patient department, where some twenty-four thousand patients receive treatment every year, afford sufficient field for clinical teaching. These institutions are well supported and free from debt. There is a medical school in Shanghai with land and building paid for. Four lecturers endeavor to instruct Chinese students. Candidates have to pass a preliminary examination. After three months' study they are re-examined, and any not qualified for the study of medicine are weeded out; those who remain have to study four years, passing semiannual examinations, and serving as hospital internes for the last year and a half of that time. The aim is to turn out carefully prepared men. A medical library and a medical museum have been started in Shanghai for the use of the Medical Association of China, and to render aid to the work in the medical school. All medical books and pamphlets are welcomed, and the curator of the museum collects and preserves pathological or anatomical specimens from all parts of the Chinese Empire. This attempt on the part of the Medical Association of China is one of very great value. Modern medicine and a knowledge of the laws of hygiene will prove of inestimable value to the millions of China. Medical teaching in China should start on a solid basis, to insure good and lasting results. We hope that the medical profession in this country will aid the medical men in China in this attempt. Medical authors could donate their works to the library. The medical schools in this country might aid the work materially by donating charts, diagrams, and teaching apparatus. Medical museums could contribute specimens, especially of diseases and injuries of bones and anatomical preparations. The medical publishers could aid by donations of books, to form a great national medical library, which in time will purchase largely to maintain itself in the front rank. We can commend the Medical Association of China and the objects for which it works to the medical profession in this country. Donations addressed to Dr. H. W. Boone, Vice-President of the Medical Association of China, can be sent to 22 Bible House, New York, and will be forwarded to Shanghai.

AIDING THE BOARD OF HEALTH.

To the Editor of The Medical Record.

Sir: In the paper read by Dr. Bryant before the New York Academy of Medicine, November 3d, on "How can the Medical Profession Aid the Board of Health?" the author urged, among other matters, the desirability of reports from physicians regarding infringements of the sanitary code and municipal ordinances regulating plumbing, construction, ventilation, etc. It does not appear to have occurred to him that there are two rather important impediments to aid from such a source—namely, the want of available information as to what constitutes an infringement of these rules; and, second, the very natural dread of being summoned as a witness, in case the matter comes before a court of law.

I believe that, as a class, physicians are the most desirous of an efficient enforcement of sanitary laws, since nearly all of the sanitary literature of the period is the production of medical men; but it can hardly be expected that a doctor who has little leisure from his practice will study the Revised Statutes and Session Reports, or keep a file of the *City Record*, in order to know what constitutes an abatable nuisance.

It seems to me that what is needed to secure professional co-operation is a publication by the Board of Health of the laws and ordinances which are in force, and an assurance that, excepting in extraordinary cases, a physician reporting their infringement will not be called upon to furnish evidence in law-courts.

I have another suggestion to make in this connection, which is that the Board of Health might serve its own interests and stimulate zeal among physicians by placing a bulletin in the Hall of the New York Academy of Medicine on which to indicate, by some graphic method, the daily sanitary statistics of leading importance, and the areas within the city limits in which zymotic diseases are most prevalent.

Respectfully,

F. A. Castle, M.D.

55 East Fifty-second Street.

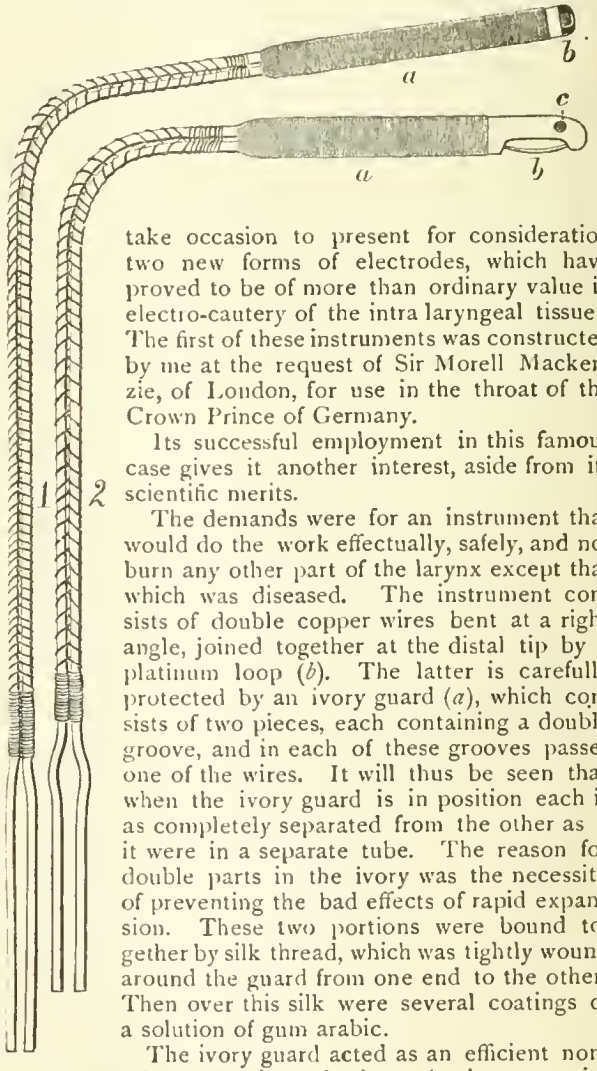
New Instruments.

SOME NEW FORMS OF ELECTRODES FOR INTRA-LARYNGEAL USE.

By ROBERT C. MYLES, M.D.,

new york.

The difficulties attending intra-laryngeal operations, by means of electrodes, are generally of such a nature as to discourage attempts at their use. It is in view of giving some encouragement to workers in laryngology that I take occasion to present for consideration two new forms of electrodes, which have proved to be of more than ordinary value in electro-cautery of the intra laryngeal tissues. The first of these instruments was constructed by me at the request of Sir Morell Mackenzie, of London, for use in the throat of the Crown Prince of Germany.



Its successful employment in this famous case gives it another interest, aside from its scientific merits.

The demands were for an instrument that would do the work effectually, safely, and not burn any other part of the larynx except that which was diseased. The instrument consists of double copper wires bent at a right angle, joined together at the distal tip by a platinum loop (*b*). The latter is carefully protected by an ivory guard (*a*), which consists of two pieces, each containing a double groove, and in each of these grooves passes one of the wires. It will thus be seen that when the ivory guard is in position each is as completely separated from the other as if it were in a separate tube. The reason for double parts in the ivory was the necessity of preventing the bad effects of rapid expansion. These two portions were bound together by silk thread, which was tightly wound around the guard from one end to the other. Then over this silk were several coatings of a solution of gum arabic.

The ivory guard acted as an efficient non-conductor of heat, allowing only the projecting extremity of the white-hot platinum loop to come in contact with the growth. The silk not only held the portions of ivory in firm position, but prevented any accidental

crumbling of the ivory and the escape of fragments into the larynx. The gum arabic served not only the purpose of a non-inflammable coating, but acted as a lubricant for the extremity of the electrode, when grasped by the ventricular bands in the laryngeal spasm. Before this instrument was used it was thoroughly tested, in the presence of Sir Morell Mackenzie and Dr. Wegner, Surgeon-General of the German army. The operation performed by Sir Morell Mackenzie with this instrument occupied but a few seconds, was unattended by any unpleasant results, and was successful in entirely destroying the growth. The second instrument is constructed virtually on the same principle, with the exception that only one side of the loop is exposed. This latter arrangement was made for burning antero-posteriorly a web growing transversely from one vocal cord to the other, in a patient of Dr. Norris Wolfenden, in the Golden Square Throat Hospital, London.

I desire to express my indebtedness to Mr Mark T. Howell of London, for valuable suggestions in the construction of this instrument.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 6 to November 12, 1887.

Greenleaf, Charles R., Major and Surgeon. Par. 8, S. O. 248, A. G. O., October 25, 1887, directing Surgeon Greenleaf to visit the recruiting depots and rendezvous at certain places, is amended to include Davenport, Ia., Quincy, Ill., and Evansville, Ind. S. O. 257, A. G. O., November 4, 1887.

Loring, Leonard Y., Captain and Assistant Surgeon. Ordered for duty at Fort Mogave, Ariz. Ter., upon the expiration of his present sick-leave of absence. S. O. 258, A. G. O., November 5, 1887.

Perley, Harry O., Captain and Assistant Surgeon. Now on duty at Fort Wayne, Mich. Ordered for temporary duty with troops stationed at Highwood, near Chicago, Ill. S. O. 258, A. G. O., November 5, 1887.

Ives, F. J., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect on or about the 15th inst. S. O. 113, Department of the Platte, November 5, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 12, 1887.

Heye, T. C., Surgeon. Detached from the Marion; proceed home and wait orders.

Craig, T. C., Passed Assistant Surgeon. Detached from the Marion; proceed home and wait orders.

Wells, H. M., Medical Inspector. Detached from the Trenton; proceed home and wait orders.

Peck, George, Medical Director. Ordered to Washington, D. C., as member of Examining Board.

Ayres, Joseph G., Surgeon. Ordered to the Galena to relieve Surgeon F. L. Du Bois.

Du Bois, F. L., Surgeon. Detached from the Galena; proceed home and wait orders.

Blindness is increasing, according to the figures of Dr. Howe, of Buffalo. In a paper read before the association for the advancement of science, that gentleman states that while the population during the ten years from 1870 to 1880 increased at the rate of 30 per cent., the increase of blindness was 140 per cent. He attributes this remarkable and somewhat alarming increase to the introduction by immigrants of large numbers of cases of contagious diseases of the eyes.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 12, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	23	2
Scarlet fever	76	10
Cerebro-spinal meningitis	1	1
Measles	20	4
Diphtheria	139	41
Small-pox	3	1
Yellow fever	0	0
Cholera	0	0

The Medical Law for New York State.—We have been asked so often by medical men, in and out of the State, concerning the medical law now in force here, that we give the text in full:

CHAPTER 647.

An Act to Regulate the Licensing and Registration of Physicians and Surgeons, and to Codify the Medical Laws of the State of New York. (Passed June 23, 1887; three-fifths being present.)

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

Section 1. No person shall practise physic or surgery in this State who shall not have attained the age of twenty-one years; and no person shall practise as aforesaid unless he or she shall be, at the time this act shall take effect, a person lawfully engaged in such practice in this State under license or authority conferred by its laws then in force, and lawfully registered pursuant to chapter five hundred and thirteen of the laws of eighteen hundred and eighty, and the acts amendatory thereof, or unless he or she shall be licensed or authorized so to practise by the provisions of this act, and registered as herein prescribed.

§ 2. From and after the date of the taking effect of this act, no person not theretofore licensed or authorized to practise physic or surgery in this State shall be deemed so licensed or authorized except one of the three following classes:

First. All who shall have been graduated from an incorporated medical school or college in this State with the degree of doctor of medicine, after substantial compliance with all the requirements of the general laws and of the charter of said corporation regulating the term and amount of study, attendance and attainment requisite to obtain said degree; provided that no person shall receive the degree of doctor of medicine, or be licensed to practice physic or surgery in this State, unless after the age of eighteen he shall have pursued the study of medical science for at least three years in a chartered medical school or with some physician and surgeon duly authorized by law to practise physic or surgery; and shall have attended two complete courses of lectures in some legally incorporated medical school or college, in good standing at the time of such attendance, prior to the granting to him or her a diploma or license; provided, further, that two courses of lectures, both of which shall be either begun or completed within the same calendar year, shall not satisfy the above requirement.

Second. All who have received said degree from the Regents of the University of the State of New York, after substantial compliance with the legal requisites preliminary to its attainment, and after examination by a legally constituted board of medical examiners of this State.

Third. All who, having been graduated from incorpo-

rated medical schools or colleges without the State as doctors of medicine, or licensed to practise physic or surgery under the laws of those European countries in which said degree does not confer the right so to practise, shall procure their diplomas from said corporations, or their licenses from such countries, to be indorsed by the faculty of an incorporated medical school or college within this State, or by the Regents of the University on the recommendation of a legally constituted board of medical examiners of this State. Every such indorsement shall be in form of schedule A or of schedule B provided by the tenth section of this act. Every corporation or board so indorsing shall keep a record of their indorsements, and may require applicants to verify their statements under oath; any indorsement made with fraudulent intent, or gross carelessness or ignorance, shall be deemed a misdemeanor, and shall subject the indorser or indorsers, upon conviction thereof, to a fine of two hundred and fifty dollars.

§ 3. Every person who, at the time this act shall take effect, shall be practising lawfully physic or surgery in this State, under the authority and license conferred by the laws then in force, but who shall not be then duly registered in the county where he or she practises; and every person who shall thereafter become lawfully authorized or licensed to practise physic or surgery in this State, shall register in a book to be kept in the clerk's office of the county in which such practice is carried on, his or her name, residence, place and date of birth, and authority for practising as aforesaid. Every person who shall apply to register as a physician or surgeon shall be required before registration to subscribe and verify by oath or affirmation, before a person qualified to administer oaths in this State, an affidavit which shall be filed and preserved in a bound volume. This affidavit shall be in the form prescribed in schedule C provided by the tenth section of this act. Every person registering as aforesaid shall exhibit to the county clerk his or her diploma or license, or in case of loss, a copy of either, legally certified as are copies of documents admitted in evidence, or a duly attested transcript of the record of its conferment from the body conferring it, upon which the said clerk shall indorse or stamp his name, and the words "Presented and registered as authority to practise physic and surgery by , on the day of , in the clerk's office of county." The said clerk shall also give to every registered physician or surgeon a certificate in the form of schedule D provided by the tenth section of this act. For all his said services the county clerk shall receive as a total fee for registration, affidavit, and certificate the sum of one dollar. It is provided, however, that nothing in this act shall require any physician or surgeon who shall have duly registered lawful authority to practise as such, conformably to the provisions of chapter five hundred and thirteen of the laws of eighteen hundred and eighty, and the acts amendatory thereof, to register again under the provisions of this act, in any county where he or she shall have registered already.

§ 4. A practising physician or surgeon having registered lawful authority to practise physic or surgery in one county, who shall remove his practice or part thereof to or regularly engage in practice or open an office in another county, shall exhibit in person to the clerk of such other county, or shall send to him through the mail by registered letter, his certificate of registration, and if such certificate shows lawful authority to have been registered said clerk thereupon shall register said applicant in said latter county, on receipt of a fee of twenty five cents. The clerk shall stamp or indorse upon such certificate the words "Registered also in county," and return the same, and every certificate and indorsement made pursuant to the provisions of this act shall be prima facie evidence in any legal proceeding that the person named has registered in the office issuing the same, the authority stated in the transcript.

§ 5. Every person now licensed to practise physic or surgery in this State under the laws thereof in force at the time of the conferment of such license, unless he or she already shall have registered his or her name, residence, place of birth, and authority so to practise pursuant to the provisions of section two of chapter five hundred and thirteen of the laws of eighteen hundred and eighty, and the acts amendatory thereof, shall comply with the requirements of said chapter on or before the first day of October, eighteen hundred and eighty-seven; and thereafter no person shall be entitled to register any authority to practise physic or surgery, except the license conferred under this act, and the laws enacted hereafter, and no registration shall be considered valid as such unless the authority registered constituted at the time of registration a license under the laws of this State then in force; provided that nothing in this section shall be construed to prohibit or suspend any prosecution for non-registration under said section instituted prior to said first day of October, eighteen hundred and eighty-seven, and further provided that no diploma or license conferred upon a person not actually in attendance at the lectures, instruction, and examination of the corporation conferring the same, or not possessed at the time of its conferment of the requirements then demanded of medical students in this State as a condition of their becoming licensed so to practise, shall be deemed lawful authority to practise physic and surgery in this State.

§ 6. No person shall be licensed or permitted to practise physic or surgery in this State who has been convicted of a felony by any court of competent jurisdiction; and if any person who is or hereafter shall be duly licensed to practise physic or surgery in this State shall be convicted of a felony, as aforesaid, his or her license to so practise, if any, shall be revoked by the fact of such conviction having been had. Any person who shall wilfully swear falsely to any statement contained in any affidavit made pursuant to the provisions of this act shall be deemed guilty of a felony, and subject to conviction and punishment for perjury; any person who, falsely and without authority, shall counterfeit, make, or alter any diploma, certificate, or instrument constituting a license to practise physic or surgery within this State, or any certificate or indorsement given in pursuance of this act, shall be deemed guilty of a felony, and be subject to conviction and punishment for forgery in the second degree; any person who shall practise physic or surgery under a false or assumed name, or who shall falsely personate another practitioner of a like or different name, shall be deemed guilty of a felony, and shall be subject to conviction and punishment for false personation; and any person guilty of violating any of the other provisions of this act, not otherwise specifically punished herein, or who shall buy, sell, or fraudulently obtain any medical diploma, license, record, or registration, or who shall aid or abet such buying, selling, or fraudulently obtaining thereof, or who shall practise physic or surgery in this State under cover of a diploma or license that shall have been illegally obtained, or that shall have been signed or issued unlawfully or under fraudulent representations, or mistake of fact in material regard, or who, after conviction of a felony, as aforesaid, shall attempt to practise physic or surgery in this State, and any person who shall assume the title of doctor of medicine, or append the letters "M.D." to his or her name, without having received the degree of doctor of medicine from some school, college, or board empowered by law to confer said degree or title, shall be deemed guilty of a misdemeanor, and upon conviction thereof shall be punished by a fine of not less than two hundred and fifty dollars or imprisonment for six months for the first offence, and upon conviction of a subsequent offence by a fine of not less than five hundred dollars or imprisonment for not less than one year, or by both fine and imprisonment. Any person who not being then lawfully authorized to practise physic or surgery in this State, and so registered according to law, shall

practise on or after the first day of October, eighteen hundred and eighty-seven, physic or surgery within this State without the license and registration provided for in this act, shall be deemed guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than fifty dollars for the first offence, and for each subsequent offence by a fine of not less than one hundred dollars, or by imprisonment for not less than one hundred days, or by both fine and imprisonment. When any prosecution under this act is made on the complaint of a lawfully incorporated medical society of this State, or a county society entitled to representation in a State society or association, the fines, when collected, shall be paid to the society making the complaint; and any excess of the amount of fines so paid over the expenses incurred by the said society in enforcing the medical law of this State, shall be paid at the end of the year to the county treasurer, for the use of the poor of said county.

§ 7. The duly incorporated medical societies of any county in which any person shall practise physic or surgery, without lawful authority or registration may, upon proof of such practice, recover from such practitioner, in an action before any justice of the peace, a penalty of twenty-five dollars and the cost of the action for the first judgment, and upon every subsequent judgment for the same offence a penalty of fifty dollars and the cost of the action; provided that said societies shall pay to the county treasurer for the use of the poor of said county any surplus that may accrue in their hands from the excess of fines and penalties collected over the disbursements of said society for council fees and the expenses incident to the enforcement of this act by them.

§ 8. Nothing in this act shall be construed to punish commissioned medical officers serving in the army or navy of the United States, or in the United States marine hospital service, while so commissioned, or any one while actually serving as a member of the resident medical staff of any legally incorporated hospital, or any legally qualified and registered dentist exclusively engaged in practising the art of dentistry, or interfere with manufacturers of artificial eyes, limbs, or orthopedical instruments or trusses of any kind from fitting such instruments on persons in need thereof; or any lawfully qualified physicians and surgeons residing in other states or countries meeting registered physicians and surgeons of this State in consultation, or any physician or surgeon residing on the border of a neighboring State, and duly authorized under the laws thereof to practise physic or surgery therein, whose practice extends into the limits of this State; providing that such practitioner shall not open an office or appoint a place to meet patients or receive calls within the limits of the State of New York; or physicians duly registered in one county of this State, called to attend isolated cases in another county, but not residing or habitually practising therein.

§ 9. The following acts and parts of acts are hereby expressly repealed, to wit: Sections eight to twenty-two inclusive of title seven of chapter fourteen of part one of the Revised Statutes; also all of chapter one hundred and thirty-eight of the laws of eighteen hundred and six, that provided for the examination and admission of medical students to practise, and for penalties for practising physic and surgery without a diploma or other lawful authority; also section or paragraph fifth of chapter one hundred and four of the laws of eighteen hundred and seven; also sections nine, ten, eighteen, and all of section eleven following, and including the words "whose duty" of chapter ninety four of the laws of eighteen hundred and thirteen; also sections one, two, four, and all of section three following, and including the words "any three" of chapter two hundred and six of the laws of eighteen hundred and eighteen; also section two of chapter two hundred and thirty-seven of the laws of eighteen hundred and nineteen; also chapter one hundred and twenty-six of the laws of eighteen hundred and thirty; also sections one, two, and four of chapter five hundred and thirty-two of the laws of eighteen hundred and thirty-six; also chapter sixty-four of the laws of eighteen hundred and forty-one; also chapter two hundred and seventy-five of the laws of eighteen hundred and forty-four; also chapter four hundred and thirty-six of the laws of eighteen hundred and seventy-four; also chapter five hundred and thirteen of the laws of eighteen hundred and eighty; also chapter one hundred and eighty six of the laws of eighteen hundred and eighty-one; also chapters four hundred and eleven and four hundred and forty-five of the laws of eighteen hundred and eighty-four; also section three hundred and fifty-six of the Penal Code. And also all acts or parts of acts authorizing any incorporated school or college to confer the degree of doctor of medicine *causa honoris* or *ad eundem*, or otherwise, than upon duly graduated students in course; and all other acts or parts of acts inconsistent with this act are hereby repealed. And it is provided that the degree of doctor of medicine conferred *causa honoris* or *ad eundem gradum*, shall not be a qualification for the practice of physic and surgery in this State. And, whereas it is the purpose of this act to codify the statutory provisions of this State regulating the admission of individuals to the practice of physic and surgery, and the punishment of those practising either physic or surgery without authority, it is further provided that the specific repeal herein of any portion of an act that may have been heretofore repealed, expressly or by implication, shall not be construed to revive the remaining part thereof.

§ 10. Section ten shall embrace the following schedules, namely A, B, C, and D.

Schedule A.—To all whom it may concern, greeting: A. B., having on the day of eighteen hundred and , presented to the faculty of , a diploma purporting to have been issued on the day of , to said A. B., conferring on the degree of doctor of medicine, and it being made certain to us by inquiry and examination that the said , at the date of said diploma, was at a medical college or school, duly incorporated, in good standing, and authorized to confer the degree of doctor of medicine, and also that the said A. B. is the identical person upon whom the said diploma was conferred, and is also a person of good moral character, who has pursued a course of study equivalent to that required of a doctor of medicine by said faculty, and is sufficiently well versed in the knowledge of physic and surgery to qualify to practise the same.

Now, therefore, the said faculty have caused this indorsement and the seal of the said to be placed upon said diploma.

(Signed) by the dean or proper officer.

[Seal.]

Schedule B.—To all whom it may concern, greeting: A. B., having on the day of presented to the faculty of a license purporting to have been issued to said , as authority to practise physic and surgery in all branches; and it being made certain to us by inquiry and examination that A. B. is the identical person on whom the license was conferred; that it is not necessary in the country in which it was conferred that a licensed practitioner of physic and surgery should have the degree of doctor of medicine, and that a license in form and substance such as the one hereby indorsed is the usual and sufficient authority to practise physic or surgery therein; and further, that said A. B. is a person of good moral character, who has pursued a course of study equivalent to that required of a doctor of medicine by our faculty, and is sufficiently versed in the knowledge of physic and surgery to practise the same.

Now, therefore, the said faculty have caused this indorsement and the seal of the said to be placed upon said license.

(Signed by the dean or proper officer.)

[Seal.]

Schedule C.—STATE OF NEW YORK, COUNTY OF , ss.: being duly sworn that h name is ; that was born in on the day of , in the year ; that now resides at number street, in the city of , and intends to practise physic and surgery in the county of ; that h authority so to practise is a license (or diploma), conferred upon h , on the day of , in the year , by , a duly incorporated medical school (or college), or a legally constituted board of medical examiners of the State of New York, authorized at the date of conferring said to confer the same, and being then in good standing (or in case of a European license, describe the source thereof, and the authority under which it was conferred). Affiant further says that is the person named in the said , and had, before receiving the same, fully and substantially complied with the requisites as to attendance, terms, and amount of study and examinations required by the laws of the State and the charter and regulations of said as preliminary and necessary to the conferment thereof. Affiant further says that no money was paid by for said except the regular fees paid by all applicants therefor; that no fraud, misrepresentation or mistake in any material regard was employed by any one, or occurred, in order that said should be conferred on affiant. (Where indorsement has been made out of a license or diploma granted without the State, this additional clause shall be verified.)

And affiant further says that the said diploma or license was indorsed on the day of , eighteen hundred and , by the faculty of , upon satisfactory proof by affiant of all the facts hereinabove recited, and that had followed a course of study equivalent to the curriculum of said , and was competent to practise physic and surgery.

Sworn to before me, this day of }

Schedule D.—To whom it may concern: Know ye, that on the day of A. B., having first subscribed to and verified an affidavit in the form of schedule C of chapter of the laws of eighteen hundred and eighty-seven, made an entry in the register of physicians and surgeons, kept in the office of the clerk of county, of which entry I certify the following to be a transcript:

NAME.	Birth-place.	Residence.	Date, source and character of license or diploma.	Indorsed by what faculty.	Remarks.

In witness whereof I have set my hand and official seal this day of

Clerk of County.

[SEAL.]

§ 11. This act shall take effect immediately.

STATE OF NEW YORK, } ss.:
Office of the Secretary of State, }

I have compared the preceding with the original law on file in this office, and do hereby certify that the same is a correct transcript therefrom and of the whole of said original law.

FREDERICK COOK,
Secretary of State.

THE INFLUENCE OF CHEMISTRY ON THE SCIENCE OF PATHOLOGY.—In Sir Henry Roscoe's presidential address on the synthesis of organic bodies, delivered before the British Association for the Advancement of Science (*British Medical Journal*, September 3, 1887), the following observations on the subject indicated by the title are made. (It will be observed that Roscoe's views on hydrophobia are by no means accepted by the bulk of the medical profession.) "Touching us as human beings even still more closely is the influence which chemistry has exerted on the science of pathology, and in no direction has greater progress been made than in the study of micro-organisms in relation to health and disease. In the complicated chemical changes to which we give the names of fermentation and putrefaction, the views of Liebig, according to which these phenomena are of a purely chemical character, have given way under the searching investigations of Pasteur, who established the fundamental principle that these processes are inseparably connected with the life of certain low forms of organisms. Thus was founded the science of bacteriology, which in Lister's hands has yielded such splendid results in the treatment of surgical cases, and in those of Klebs, Koch, and others has been the means of detecting the cause of many diseases both in man and animals, the latest and not the least important of which is the remarkable series of successful researches by Pasteur into the nature and mode of cure of that most dreadful of maladies, hydrophobia. And here I may be allowed to refer with satisfaction to the result of the labors on this subject of a committee, the formation of which I had the honor of moving for in the House of Commons. These results confirm in every respect Pasteur's assertions, and prove beyond a doubt that the adoption of his method has prevented the occurrence of hydrophobia in a large proportion of persons bitten by rabid animals, who, if they had not been subjected to this treatment, would have died of that disease. The value of his discovery is, however, greater than can be estimated by its present utility, for it shows that it may be possible to avert other diseases besides hydrophobia by the adoption of a somewhat similar method of investigation and of treatment. This, though the last, is certainly not the least of the debts which humanity owes to the great French experimentalist. Here it might seem as if we had outstepped the boundaries of chemistry, and have to do with phenomena purely vital; but recent research indicates that this is not the case, and points to the conclusion that the microscopist must again give way to the chemist, and that it is by chemical rather than by biological investigation that the causes of diseases will be discovered and the power of removing them obtained. For we learn that the symptoms of infective diseases are no more due to the microbes which constitute the infection than alcoholic intoxication is produced by the yeast-cell, but that these symptoms are due to the presence of definite chemical compounds, the result of the life of these microscopic organisms. So it is to the action of these poisonous substances formed during the life of the organism, rather than to that of the organism itself, that the special characteristics of the disease are to be traced. For it has been shown that the disease can be communicated by such poisons in the entire absence of living organisms."

DEATH FROM LEECHES.—The following case, in which death was seemingly caused by leeches, has been recently published. A woman who lived at the lodgings of a dealer in leeches was found dead on the floor, the lower part of her body and her lower extremities being naked. On her legs there were present upward of one hundred recent wounds inflicted by leeches. The latter were creeping about on the floor. The vessels in which the animals had been kept were uncovered. The deceased had led a drunken life; hence it is possible that she herself applied the leeches to her body.

PROUD OF "THE RECORD."—We acknowledge the receipt of printed slips of the proceedings of the International Medical Congress, issued daily by THE MEDICAL RECORD. THE RECORD spared neither time nor money in keeping up with the procession. Its issue of September 10th contained sixty pages of reading matter devoted to the proceedings of the International Medical Congress. The profession of this country may well be proud of THE RECORD.—*Indiana Medical Journal.*

THE PREVENTION OF MICROPHYTIC DISEASES BY INDIVIDUAL PROPHYLAXIS.[1]

By EZRA M. HUNT, M.D.,

SECRETARY NEW JERSEY STATE BOARD OF HEALTH, TRENTON, N. J.

During the last twenty-five years no subject has been more prominently before the students and practitioners of hygiene than the consideration of new methods, or new applications of old methods, for the prevention of disease.

This inquiry, to some extent, involves investigation into the specific entity of disease. But a still more hopeful direction of investigation is to find out what fertilizes it or makes it more likely to be severe, what sterilizes it or makes it more likely to be mild, or what will make the human system resistful to the sedation or propagation of the disease so that it will not occur.

The first great discovery in this direction was that of the modifying influence of inoculation.

It could not have been merely the cathartic and the changed diet of a few days that reduced the mortality from inoculated small-pox to such a minimum. The prevalence of the custom was at once the certification of the terror of the caught disease and the innocency of the conferred or inoculated disease. Yet it was the same disease without any effort at attenuation.

It was the introduction of the virus into the *skin* or areolar tissue, instead of by *inhalation*, that seemed to result in modification. Its approach was through the periphery, instead of by a central and vital organ. The chief safety was in the fact that the involvement of the lungs and the secondary fever were avoided.

Somehow, by the metastasis or diversion or mode of attack, the system grew tolerant of the malady, and was able to throw it off with comparative harmlessness.

It has fallen to my lot frequently to see the same remarkable mitigation in the inoculation of cattle with the virus of contagious pleuro-pneumonia.

When the infection is conveyed by the breath it seizes upon the lungs and pleura. Frequently, in three days after it is manifested, the spongy organ of two or three pounds has become so solidified with tenacious lymph that it has a weight of thirty pounds, and death is the speedy result.

But introduce this virus into the muscular tissue of an extremity and all symptoms are more gradual. There are local swelling, the throwing out of lymph amid muscular tissue, and slight constitutional disturbance; but the lungs escape, and fatal cases are exceedingly rare. Not only this, but other animals will not contract the disease, and immunity is secured.

These facts as to the effect of the different modes of conveyance of a disease have their practical bearings and still invite investigation.

It was another wonderful fact when *scurvy* yielded to the preventive art. The great naval hospital at Haslar, England, had been built with special reference to the fearful inroads that this disease was making amid the British fleets. When, in 1796, Sir Gilbert Blane and other medical officers of the navy obtained the order that lime-juice be supplied to the seamen, the terror of that disease was taken away. Studying the facts by the history and peculiarities of that disease, we cannot dismiss it as a mere error of dietetics. It was not simply that fruits and fresh vegetables prevented the disease. It was a far-reaching lesson as to how diseases may be modified by medicines as well as by foods; how the presence of something *administered* may prevent a disease.

As to the next wonder of the preventive art, that of Jennerian vaccination, it is so often presented as to need only our passing recognition. Yet it is to be remembered that it is a subject not yet exhausted. Whether something of the modification is owing to the mode and place of introduction, whether it is a modified small pox, whether it is attenuated virus and may be in different degrees of attenuation, and so differently protective, these and other questions are left over to be determined in this period when the microscope, the pathological, the chemical, and the biological laboratories have come to the aid of the clinician, and we can study and compare the accumulated facts.

The *Pasteurian vaccination* may stand next, if not in order of time, since Pasteur opened his Copenhagen address by profound acknowledgment of his indebtedness to Jenner as the great forefather of preventive medicine.

Here the mode and place of introduction, degree and permanency of effect, and the nature and cause of the so-called attenuation, are still before us with unanswered inquiry.

Next, while the doctrine of the prevention by *isolation* is old, yet new methods and new results, as to it, almost make it a *new preventive* art. Sea and land quarantines are modified, and ought to be. How far it is to be isolation of the person, or only isolation of the personal effects, is unsettled. What the forsaking of an infected house or ship will do, what the camping out of all the well from a sick city will do, what isolation alone will do, as in Leicester, with small-pox, and what is the most perfect plan of organized, systematized isolation, all these are before every health officer as large and most practical questions.

Next comes *disinfection*, in all it means by the new light of biology and the study of micro-organisms—whether it be the destruction of animal or vegetative parasitic life—of these as larvæ, as spores, or as sporeless plants, at any and all stages of existence and development.

Also what is meant by inhibiting or thwarting action, even when we do not destroy life. Also what disinfectants can do with the surroundings in destroying the pabulum or nutrient media. Also what these can do *in the system*, either to destroy the microbe which is setting up pernicious activity there, or in some way to deprive it of its food or limit its power.

For the present we confine ourselves to the last item. So soon as it became certain that many diseases depend upon, or are associated with, micro-organisms, the inquiry was in order whether there could not be some method utilized and applied by which the presence or activity of these in the blood-tissues or secretions could be so interfered with as to prevent or mollify disease. Passing for the present certain facts as to septic and non-pathogenic organisms, which, introduced into the system, may of themselves, or by their ferments or alkaloids (ptomaines), cause disease, we confine our inquiry to the ques-

[1] Read before the American Public Health Association, at Memphis, November 8, 1887.

tion whether it is possible to thwart the action of the *specific* or *pathogenic* micro-organisms in their attempt to invade, or after they have invaded, the system.

We get some light or some analogy as to this from considering the life-history and behavior of these organisms outside the system.

First of all, we find that pathogenic organisms are "dependent for their growth on the presence of the suitable nourishing material." In this respect they are far more selective than the septic organisms, which "find in almost all animal and vegetable fluids the substances necessary for nutrition." It is further found that there are substances which inhibit the growth of, or altogether destroy, these micro-organisms, such as corrosive sublimate, salicylic acid, etc. To do this they do not always need to be germicides.

Far *short* of *destruction*, such substances are capable of restraining the morbid action so far as to thwart their pernicious activity, which in the case of an invading disease is really the gravity of the disease.

Klein gives abundant evidences and references, on page 208 of his book on "Micro-organisms and Disease," to show that "pathogenic micro-organisms are capable of suffering some modifications in their morphological and physiological behavior." He adds: "Now, it is known of many micro-organisms, bound up with infectious diseases, that temperature, the medium in which they grow, and the presence or absence of certain chemical compounds are capable of materially affecting them" (Klein, p. 207).

Inasmuch as this growth and multiplication are known to go on in the bodies of living animals, and to constitute the identity and gravity of many diseases, it is a radical and very essential and hopeful inquiry whether we may not, by some change in the animal, or in some of those chemical compounds referred to, either destroy the micro-organism or inhibit its activity.

It is very suggestive of the possibility of this to remind ourselves of the probable reason why some are unsusceptible to disease. Dr. Klein (p. 247) argues that it is because there is "something or other present in a particular tissue to which the latter owes its immunity."

He infers that although this is "dependent upon the life of the tissue, it is not identical with any of the characters constituting its life." He says: "The most feasible theory seems to me to be this, that the inhibiting power is due to *the presence* of a chemical substance produced by the living tissues." This puts the body in such a condition that in the particular case "the organisms cannot thrive and produce the disease." It is true that he suggests that the germicide or inhibitive material is a product of living tissue. This is not necessarily so, or if so would not necessarily be a product of the living tissue of the human body.

If the non-activity of the organism, and so the non-occurrence of the disease, is owing to "the presence of a chemical substance" in the tissues or blood, it is a very pertinent and natural inquiry whether we cannot and do not produce the same result by putting, and for a time sustaining in the system, certain "chemical substances" which, so introduced, interfere with the processes sought to be set up, and which would constitute the disease.

The analogy is strengthened by the fact that chemical products are so much coming to be suspected or recognized as constituting the virus or specificity of diseases in which the micro-organisms are the initiative factors.

Still more, however, it behooves us to find out whether, either in chemical or laboratory experience, there has been any confirmation of such views. In clinical experience we have long had not only the fact that quinine will cure chills and fever, but that it is a substance which, introduced into the human system in advance, will prevent those processes which constitute the disease. So soon as it was made probable that the malarial diseases belong to the species or genera of microphytic diseases, so soon it seemed probable that the result was due to this inhibitive effect of the alkaloid.

As a result of experiences with epidemics of diphtheria and scarlet fever, so long ago as at our Chicago meeting in 1887 (see vol. iv., American Public Health Association, p. 348), I presented a paper on this mode of arresting and preventing pestilential diseases (see also two articles on the subject in THE MEDICAL RECORD, vol. ii., 1877).

The next year the subject was more fully presented in a paper read at the Richmond meeting.

In the intermediate time Professor Cabell was so impressed by the facts presented, as to note it in his address before the American Medical Association in the spring of 1878. A reference to the paper of 1878 will show how fully this idea was insisted upon and illustrated. It was claimed that by the use of certain medicines we could prevent the sedation or interrupt the development of that which constituted the infection. Many of the facts in support of this view at that time were collated, and since then, from time to time, medical men have corroborated these views from their own experience.

It is of value that since then we have come into a knowledge of several other diseases as microphytic, and this has greatly fortified the position then taken.

Says L. Brunton: "Facts seem to point to ferments or enzymes as the agents by which the tissues are built up and pulled down in their constant change, which continues during life; and the action of drugs on these enzymes is becoming one of the most important questions of pharmacology" (see American Public Health Association, vol. vi., p. 103).

From time to time in the last five years the journals have contained records as to this possibility of individual prophylaxis.

But all this was only the clinical experiences of physicians. Too often these are not accorded the same consideration as what are called crucial or laboratory experiments.

It has recently been necessary for Sir James Paget, as President of the Pathological Society of London, to contend that clinical observation is scientific, and that the sick-room is a laboratory with its crucial experiments, as real as those in which culture-experiments are instituted.

But now experimental tests have come directly to our aid in determining the effects of prophylactic remedies. Before this we knew that arsenic, potassium chloride, quinine, and excess of iron, etc., could be made constant for days and weeks in the blood by medication.

In 1884, under the direction of the Local Government Board of England, Dr. J. T. Cash instituted a series of experiments as to chemical disinfectants, and made report thereon. The object of the earlier investigations, recorded in a late report, was to inquire whether certain substances, belonging to the aromatic series, when introduced into the body of a living animal, were capable of preventing the development of a particular virus within that animal. Later research was extended to a metallic salt (corrosive sublimate), which acts otherwise than aromatics with regard to albuminous bodies.

It was with this that the most decided result was secured. The result sought was to find "its power of resisting, in the condition in which they occur within the animal body, the multiplication of the active principle of the virus against which they are directed to such an extent that the virus is destroyed, or only reproduces itself so fully as to cause a modified or abortive attack of the disease in the animal body experimented on." The disease chosen for the experiments was *anthrax*, the severest test of all. The results of the first series of experiments was such as to show that the previous administration of corrosive sublimate may considerably modify the course of the anthrax disease in rabbits. The paper concludes by saying, "that although these few experiments are not

conclusive, they cannot fail to encourage the hope that we may yet succeed in creating with precision, within the animal economy, by the action of this and perhaps other drugs, a temporary condition of resistance (in this case seven weeks), which may so far limit the activity of the anthrax virus that it will merely produce a passing, and at the same time protecting, disorder, instead of a fatal disease."

The next year (1885) Dr. Cash made to the Local Government Board a further report on mercury as a means of prophylaxis to anthrax. In this he says: "I have followed up the investigation of the prophylactic action of the perchloride still further, and the favorable opinion I was before led to entertain of its efficacy has been abundantly confirmed."

Dr. Klein has also satisfied himself of the restraining powers of the perchloride of mercury. Tomassi-Crudelli and others claim that arsenic has the same control as a preventive of malaria. These results may be taken as a confirmation of the clinical evidence given, and of the view we long since expressed as to the coming importance of various allied modes of prophylaxis in the prevention of various communicable diseases.

Heretofore we have mentioned some other prophylactics which we believe to have been effectual in preventing or mitigating some of the parasitic diseases. With this new evidence I believe the time has come for a thorough testing, both by the practitioner and the biological investigator, of this new method of preventing and controlling disease. There are now many who believe that the real action of some of our most successful remedies is just this: The mitigation or prevention of a microphytic disease does not necessarily mean the destruction of the organism, but its inhibition *in loco*, or the modification of its chemical action on the tissues or of its products so as to render it harmless.

It is a part of that antiseptic medication which Professors Yeo and Brunton, and many others, recognize as steadily gaining ground for approval.

If, in an individual case of exposure, or an outbreak in a family or a neighborhood, this kind of prophylactic treatment is available, it is easy to forecast the wonderful beneficence of the result.

If, for instance, in an outbreak of diphtheria in a family or in a neighborhood, we can put all persons exposed to it for a few days upon a prophylactic treatment, or if in the first outbreak of cholera in a locality, all exposed persons can be rapidly brought under the inhibitive effect of a prophylactic administered promptly and continuously, we will have in our possession a mode for the limitation or prevention of epidemics far more likely to have practical application than any system which involves the cutting of the skin, or the introduction in any form of the actual virus of the disease. At any rate, with two such modes of defence at hand, we might hopefully expect to substitute the word sporadic for epidemic, and to bring many a vagrant pestilence within the range of our control.

The present age of advancing medical art will be rendered still more notable if it can be found that simple and active medication, on the outbreak of any communicable disease, will protect all those exposed thereto from contagion, or so modify its effect as to make the attack benign.

THE TREATMENT OF HEPATIC CONGESTION.—The following mode of treating congestion of the liver is practised by Dr. Jules Cyr: Application over the liver of compresses of cold water, often renewed. Two or three leeches about the anus. At evening, three-fourths of a grain of calomel should be taken, followed the next morning by five drachms of Glauber's salts. As beverage, milk and Vichy water, or seventy grains of ammonium chloride in a quart of water. A douche, while patient is reclining, of water at a pleasant temperature given over the hepatic region.—*Revue de Thérapeutique.*

REPORT ON HYDROPHOBIA: PASTEUR'S METHOD.

By CHARLES W. DULLES, M.D.,

SURGEON TO OUT PATIENTS IN THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA AND IN THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

IN accordance with the resolution adopted at the last meeting of the Medical Society of the State of Pennsylvania, requesting me to continue my studies in regard to hydrophobia, and to communicate the result at this meeting, I have the honor to present to you the following report:

The year just past has been marked by animated discussion of the value of M. Pasteur's preventive method, and by an almost total neglect of study of the nature of the disorder called hydrophobia or rabies, or of any other method than that of Pasteur for combating it. This fact appears to me to be deplorable. In my opinion, it would be of great value to science if studious men would devote more of their attention to the larger subject of so-called hydrophobia and somewhat less to that phase of it which is connected with the theory of preventive inoculations. And I trust I shall be pardoned for expressing some disappointment that a paper on "The Disorders Mistaken for Hydrophobia," which I read before this Society in 1884, has not prompted some more competent investigator to follow up the lines there laid down, in order that the true and the false in regard to hydrophobia may be more clearly distinguished from each other.

Unfortunately, as I have said, the whole world has for the last year or two been bent on deciding whether or no Pasteur has discovered a reliable prophylactic for a disorder the nature of which is not at all understood, and the diagnosis of which rests on no better basis now than it did in the Dark Ages.

This being the case, however, I will try to give you a succinct account of what has developed in regard to Pasteur's method since we last met. One of the most remarkable events of the year just past was the abandonment by Pasteur of the method which he had before declared to be infallible, and the adoption of a new one, which he calls "the intensive method," and which in turn he declared to be infallible before the Académie de Médecine, November 2, 1886.

The original method consisted in injecting hypodermically a small quantity of a mixture of sterilized *bouillon* with a piece of dried spinal cord of a rabbit which had died after inoculation by trephining with the so-called virus of rabies. One injection was made daily for ten days, beginning with a mixture made with a piece of a cord which had been dried for fifteen days, and ending with a piece of one which had been dried only six days. *The intensive method* consists in passing from dried spinal cord of the twelfth day (twelve days dried) to that of the first day (fresh) in three days, and then passing from a cord of the eighth day to a fresh cord in three days more; while a third course, following immediately the others, passes from a cord of the fourth day to a fresh cord in four days more. The whole set of inoculations is thus made in ten days; and Pasteur says that in extreme cases the whole intensive method may be used in one day. According to the claims of Pasteur, the intensive method has proved more successful than his former method. According to Pasteur's critics, it has not only been less successful, but it has also proved to be very dangerous, having actually *caused* the death of a number of patients.

I do not care at this time to go into a discussion as to the actual mortality of persons treated by Pasteur after bites of animals assumed to have been rabid; but I must repeat what I have said before, that the claim that Pasteur has discovered a preventive of the outbreak of hydrophobia after inoculation by the bite of a rabid animal rests upon two principal fallacies. One of these fallacies is the assumption that hydrophobia is a specific,

inoculable disease. I need not repeat the arguments which I have made before this Society, the American Medical Association, the Philadelphia County Medical Society, and the College of Physicians of Philadelphia, to show that what is called hydrophobia is not a regular sequel of the bites of animals supposed to be rabid; that it appears after a variety of traumatisms and in the course of a variety of diseases; and that it sometimes occurs spontaneously. These arguments have never been refuted, although I cannot say what may become of them if the world stops studying Pasteur and takes up the study of hydrophobia. So long, however, as they stand unrefuted, I may save your time and mine by simply referring to them. I also call your attention again to the fact that if it were admitted that hydrophobia is a specific, inoculable disease, like syphilis, or small-pox, or anthrax, Pasteur has turned his back on the natural vehicle of the contagion—the saliva—to experiment with dried spinal cords, which no dog, or wolf, or pig, or cow, ever yet used upon his victim, or could use, were he ever so mad.

There can be no doubt that Pasteur can kill rabbits by inoculating them with portions of the spinal cord of sick animals, or that he can protect a certain proportion of rabbits against death from such inoculation by accustoming their systems to the effects of the poison by means of previous inoculations with smaller quantities of it.[1] This is a very old and familiar laboratory and clinical experience. But in my opinion the disease with which Pasteur has been working is an artificial disease, and has nothing whatever to do with rabies or hydrophobia.

The second fallacy upon which Pasteur's claims rest need not be exposed, if what I have just said is true. But, if it is not, then this second fallacy must be considered. It consists in the assumption that, in spite of all theories, in spite of all objections founded on logic, Pasteur's method has actually saved a large number of persons, who but for it would have died of hydrophobia. When I last addressed you, Pasteur had treated 950 cases of persons supposed to have been bitten by rabid animals, by the method he then considered perfect and sure, and seven of his patients—according to his own admission—had died of rabies.

On January 11, 1887, Pasteur reported to the Académie de Médecine, by M. Grancher, that up to January 1st he had treated, from France and Algeria alone, 1,956 persons, with only 17 deaths—that is, less than one per cent. Enthusiastic admirers of Pasteur's method have claimed that from July, 1885, to January, 1887, he has "cured" 3,000 persons (see *Journal de Méd. de Paris*, January 16, 1887, p. 81).

These figures do not correspond with those of some of Pasteur's critics. For example, *The Zoöphilist*, of London, March 1, 1887, contains a list of 53 deaths after treatment by Pasteur, and of 16 more treated by his method in Russia, making a total of 69 deaths. On going over the statistics of Pasteur's anti-rabic inoculation, the careful observer will not fail to be struck with the wonderful rapidity with which they increased at the time when they were most actively advertised. On March 2, 1886, Pasteur reported that in the eight months from July 7, 1885 (when he began the treatment of his first subject, the boy Meister), to March 2, 1886, he had treated 350 cases—an average of 44 a month. On April 12, 1886, he reported a total of 726 cases, or 370 new cases in six weeks—an average of more than 123 a month. On May 4, 1886, he reported a total of 950 cases, or 224 new cases in three weeks, the average being nearly 300 for a month!

These are figures which represent an annual death-rate from hydrophobia of 1,846, almost exclusively from France—assuming as true Pasteur's statements as to the care he exercised to treat only cases in which there was no doubt as to the danger of the patient.

That this calculation is not forced will be seen from the fact that Pasteur has claimed that, from July, 1885, to November, 1886, he had treated 2,490 persons bitten by mad animals, among them over 1,700 Frenchmen, with only 10 deaths. If this were true, we would have to admit that Pasteur, whether logically right or wrong, has saved a very large number of persons from death. But it cannot be true; for, in the first place, the *Journal de Médecine de Paris*[1] immediately followed this announcement by the publication of the names of, and other data in regard to, 13 persons who had died while under treatment by Pasteur, and gave a detailed list of 34 other persons who died after treatment by Pasteur, making a total of 47 deaths. In France alone there died, during one year of Pasteur's practice, 29 persons, with and without treatment by him, which was two more than the average number of deaths per year, as determined by official statistics, before Pasteur's method was discovered. In view of these facts it will be seen that the deaths from hydrophobia in France have actually increased since Pasteur began to practise his "infallible" cure.

Again, it is impossible that so many as 1,700 Frenchmen should have been inoculated with hydrophobia by the bites of rabid animals in the fifteen months from July, 1885, to November, 1886. This would equal 1,360 persons in a year. Now, the very lowest estimate of the proportion of deaths after the bites of rabid animals is an old (and unreliable) one of John Hunter's, viz., one in twenty. If this were correct, we would have, in 1,360, 68 persons in France doomed to death in one year but for Pasteur's treatment.

As an illustration of the way in which even a more staggering assumption is presented by the supporters of Pasteur in Paris, let me cite part of an argument by Vulpian before the Académie de Médecine, January 18, 1887. Vulpian asserts the ordinary mortality after the bites of rabid animals to be sixteen per cent., and that after treatment by Pasteur to be only one per cent. Pasteur having treated 1,726 French patients, Vulpian says he must have saved the lives of at least 276 French persons, who but for him would have died of hydrophobia. Now, if we add to this number the 30 deaths which actually occurred, we have a total of 306 to represent the mortality of hydrophobia in France in one year, from October, 1885, to October, 1886. This is ten times the average mortality, and yet Vulpian does not hesitate to claim that Pasteur's success can only be estimated by assuming these astonishing figures to be correct. The hardihood of this assumption is in keeping with the boldness with which, as I have before stated, Pasteur and his imitators fill up with an assertion any gap in their demonstration. It has been claimed by Pasteur himself, and repeated by his supporters, that the apparent rarity of hydrophobia heretofore has been due to the fact that cases of this disorder were formerly concealed. Can anyone believe this? Is not every case of supposed hydrophobia sure to be known? Is it not, indeed, sure to be published far and wide? And need I argue to convince you of the preposterousness of this claim of Pasteur, when confronted with the logical inference from the figures he has presented to the world?

It is impossible to believe that there should be such an enormous increase in the number of persons liable to have hydrophobia in France just when Pasteur's method came into vogue, especially when we consider that the number of cases has sometimes fallen, as in 1870, as low as six. On the contrary, it seems to me to be clear that in addition to an actual increase of deaths since Pasteur began his work, there has been an enormous increase of the fear of hydrophobia. The figures which I have given above make the total deaths, after inoculation by Pasteur's method, in eighteen months, from September 1, 1885, to March 1, 1886, number 69; and who can esti-

[1] This is what Pasteur claims his "attenuation" to be. See Bul. de l'Acad. de Méd., Oct. 27, 1885, p. 1437.

[1] See Cincinnati Lancet-Clinic, January 22, 1886, pp. 127–130.

mate how many of these would never have had hydrophobia at all, if it were not for the morbid fear excited by the attention which has been directed to the horrors of this disorder by the sensational manner in which the newspapers—some of them, as the Paris *Figaro*, with Pasteur's own assistance—have paraded the details of hydrophobia before the public? A sad illustration of the effect of these publications occurred in Baltimore, in April, 1886, when a young physician who had been a diligent devourer of the newspaper literature about Pasteur died from pure fright three months after receiving some slight scratches from the teeth of a dog which gave no evidence of having rabies at all.

I have tried on several occasions to point out the many fallacies in the reasoning of Pasteur and of his defenders, and I have now once more tried to show how sadly his method has failed to prove a benefit to humanity. I have shown that the number of deaths from so-called hydrophobia has actually increased since Pasteur's method has been practised, and the enormous increase in the number of those who have thought themselves to have been exposed to it in Pasteur's own country. You all remember how frequent were the cases of so-called hydrophobia, even in our own country, a year ago, when everybody was talking about Pasteur's method. And now, when the excitement has died out, when the method is falling into discredit, even in France, how rare they are becoming. Is this a mere coincidence? I truly think not. But the fact confirms my belief—not easily acquired nor lightly held—that the way to banish hydrophobia is not to cultivate and inoculate its so-called virus, but to cultivate sensible ideas in regard to its true nature, and to inoculate our fellow-men with the idea that it is very, very rare, that it does not necessarily follow the bite of a rabid animal, that it need not follow the bite of any animal, that it is amenable to treatment, and that its very existence seems to vanish in the light of strong common-sense. We have not had a single case in Philadelphia since the profession there has discussed the subject thoroughly; and we have no need of Pasteur institutes, such as have afflicted Paris and Odessa, and our unfortunate sister city, New York. And I fondly hope that our State—which I think has not seen a case in the past year—will soon cease to know of hydrophobia or to believe in it, and that with the advance of true science mad dogs and mad men will disappear from the earth, as witches have, not so long since, disappeared.

So much for my own opinion in regard to the value of Pasteur's method of treating so-called hydrophobia. Let me now give you, in brief, the opinions of some other men who have studied it carefully, and a *resumé* of the standing of the method in the civilized world.

Mr. Vincent Richards, in a pamphlet published in Calcutta in 1886, and entitled, "Hydrophobia and M. Pasteur," says: "M. Pasteur has by no means proved that the measures he advocates as a prophylactic against hydrophobia are successful. Indeed, he has not yet advanced one single fact that entitles him to claim proof on scientific grounds;" and again: "It is simply astonishing that, on the mere *ipse dixit* of M. Pasteur, in the face of the stern logic of facts and the inherent probabilities of the utility of such an extraordinary and elaborate system of treatment . . . scientific bodies should have so blindly accepted as gospel truth all that he has chosen to promulgate."

Dr. Benjamin Ward Richardson, in the *Asclepiad* for 1886, No. 10, vol. iii., says of Pasteur's method: "No insinuation as to motives, no fears of opposing the popular voice, should stop the better voice of the demand for the most perfect proof of the truth, the whole truth, and nothing but the truth." Of the deaths after treatment by Pasteur, he says: "For these deaths there are excuses, but no satisfactory or clear explanations." He shows the absurdity of comparing Pasteur's method with the practice of vaccination, and concludes a series of pertinent questions with the remark, "If to these natural inquiries there be no definite answers, then a more imposing house of cards was never erected than has been run up to indicate the cure of hydrophobia per similia."

On June 10, 1886, Dr. E. C. Spitzka read a paper before the New York Society of Medical Jurisprudence and State Medicine, in which he criticised Pasteur's method and demonstrated by animals upon which he had experimented that the symptoms of paralysis which Pasteur has repeatedly claimed as manifestations of rabies could be produced by inoculation of dogs with a variety of non-specific materials. This paper of Spitzka's was published in the *Journal of Comparative Medicine and Surgery*, July, 1886, and is followed by an editorial, presumably by W. Clement, V. S., of the Montreal Veterinary College, which is written in manifest sympathy with the views expressed by Drs. Spitzka and Brill, and by me, at the meeting referred to.

The Belgian Government, in consequence of requests made in the Chamber of Deputies, lately deputed three Belgian physicians residing in Paris—Drs. Grandjeau, De Bruyn, and Peeters—to investigate and report on M. Pasteur's method of preventive treatment of hydrophobia, and to decide upon the advisability of founding a Pasteur institute in Belgium. The report of these gentlemen, as the Chamber has just been informed, is decidedly adverse to this step. It was decided by the reporters that Pasteur's method is not as yet sufficiently established, and one of them, Dr. De Bruyn, doubted whether there was any efficacy at all in the treatment. In this last view, Van der Corput, "Belgium's chief specialist," coincides (*British Med. Journal*, April 2, 1887, p. 740).

In Paris, at the meeting at which Pasteur announced the treatment and cure of his first patient, the boy Meister, Jules Guerin advised the exercise of prudence in accepting Pasteur's conclusions, and begged the Académie de Médecine not to commit itself unreservedly to them; and since then Colin (one of the best men in the Académie) has protested most vigorously, and, to my mind, most convincingly, against the fallacies of Pasteur's method. Most recently, Peter has collected and laid before the Académie the histories of a number of cases in which it seems likely that Pasteur's inoculations have actually caused the death of those who came to him to be cured. But the most scathing critic in Paris is Dr. A. Lutaud, editor of the *Journal de Médecine de Paris*, who for more than a year has devoted its pages to exploring the methods and the results of Pasteur, and who has recently embodied his criticism in a book entitled "M. Pasteur et la Rage" (Paris, 1887). In this book Lutaud not only charges Pasteur with scientific error, but also with unscientific methods in propagating his views, with concealment, with tergiversation, and with mercenary conduct. What may seem to some to be a certain extravagance in Lutaud's denunciation of Pasteur he justifies on the ground of the gravity of the question involved, and by the plea that such extraordinary claims, urged in such an extraordinary way, require severe and unsparing denunciation.

In Germany, Pasteur's method has obtained no foothold whatever, not, as his apologists have claimed, because Germany is hostile to French achievements, but because Germany is almost free from hydrophobia, presenting in this a strange contrast to what the adherents of Pasteur must believe to be the case in France. In Prussia a member of Parliament inquired about the attitude of the government toward the method of Pasteur, and one of the ministers replied: "This question is of no importance to Prussia, because the mortality from hydrophobia has fallen to nothing in this country. . . . The government thinks there is no occasion to send anyone to study the new method for its treatment. It intends to wait until the discovery, so pompously announced, shall be confirmed by time."

In Austria, Pasteur's method did obtain a certain foothold, and a sort of Pasteur institute was started there. But at about the time we were last discussing Pasteur's

method, Frisch, of Vienna, who had learned from Pasteur how he conducted his experiments, and had obtained from him material with which to repeat them, was exposing the fallacies of Pasteur's logic and the unreliability of his experiments (see editorials in *The Medical News*, of Philadelphia, June 12, 1886, p. 658, and September 4, 1886, p. 266). Strangely enough, the sentiments of Frisch were so perverted by the organs of Pasteur in Paris that they were at first represented as confirming Pasteur's claims. When their true nature was beyond concealment, they were criticised as founded on imperfect methods of experimentation. Frisch then proceeded to accept the new conditions proposed by Pasteur, and made a new series of experiments, the result of which was the announcement by Frisch that no real ground exists for a belief in the efficacy of preventive inoculation in the human subject, while there is a strong probability that the inoculation may transmit rabies to human beings (see *Berliner klinische Wochenschrift*, February 7, 1887, and *The Medical News*, March 26, 1887, p. 347).

In Russia, Pasteur institutes have been founded in at least five places, but the results obtained have been so unsatisfactory that only blind partisans of the method have been satisfied with them.

In Italy, also, several Pasteur institutes have been founded, but here, too, the results have not recommended them to prudent men. In the Bulletin of the *Académie de Médecine* of Paris, for February 8, 1887, will be found a communication of Professors Renzi and Amoroso, in which they express the opinion that Pasteur's method is worthless. In a letter to the *Corrierè del Mattino*, February 15, 1887, they say that Pasteur's inoculations have not delayed or hindered the manifestation of rabies, but that they have clearly contributed to render the disease more rapid and more fatal.

In England, Pasteur's method at first met with much favor, and created so much stir that cases of hydrophobia sprung up on every side. Numbers of English persons went to Pasteur to be treated by him, and Parliament appointed a commission to go to Paris and investigate his claims. This commission has not yet reported, although at one time there was a belief that it would substantially indorse Pasteur's method.[1] Its silence thus far may have been somewhat influenced by the exposure, by Dr. Anna Kingsford, of the truth in regard to a few of the cases of English persons supposed to have been "cured" by Pasteur, or by the criticisms of Dr. Thomas Dolan, the author of the most complete book on hydrophobia in the English language, or by the unfortunate death of several Englishmen who had been treated by Pasteur, and who died with symptoms of the artificial disease which Pasteur produces in rabbits by his inoculation.

In America we have had but two Pasteur institutes. One was that in St. Louis, to which I referred in my "Comments on Pasteur's Method of Treating Hydrophobia," before the Philadelphia County Medical Society, January 13, 1886 (see MEDICAL RECORD, February 13, 1886), and which seems to have been still-born. The other was incorporated with much display in New York, January 2, 1886; but this, after a lamentable experience, has disappeared from notice. As Spitzka says: "In New York the death of a Pasteur institute was almost simultaneous with its birth" (*The Forum*, April, 1887, p. 184).

A year has passed since we last met and discussed Pasteur's method, and I am glad to be able to say that it seems to be tottering to its fall. And this I declare, not because I take pleasure in any man's discomfiture, or in the bitter disappointment of those who believed Pasteur had solved the riddle of this obscure disorder, but because I have always regarded his method as an obstacle to true progress, and because I believe that the longer it is believed the bitterer will be the hour of disillusion. I have nothing to say of Pasteur as a man, but my regard for what I conceive to be the truth, and my interest in our fellow-men, leads me to oppose his claims in regard to the treatment of hydrophobia, and to repeat publicly, what I have twice before said, that "this method ought to be rejected and condemned, in the interest of humanity as well as of science."

[1] In the British Parliament, August 26, 1886, Mr. Charles Momson Ritchie, President of the Local Government Board, replying to an interrogatory by Sir John Lubbock, stated that the committee appointed by the Government to examine into the Pasteur method of inoculation for the prevention of rabies was fully satisfied that the French savant's treatment for hydrophobia was effective. Mr. Ritchie added that the Government hoped soon to have a full report from the committee (Philadelphia *Public Ledger*, August 27, 1886).

THE ANTIQUITY OF MEDICAL SCIENCE.

By J. A. S. GRANT-BEY, A.M., C.M., M.D., LL.D., Etc.,

CAIRO, EGYPT.

PROFESSOR VIRCHOW, in discoursing not long ago to a learned body at Berlin, said that medicine was the only science that had a continuous history for three thousand years; but I shall endeavor now to show you that we have a more or less continuous history of medicine for nearly six thousand years.

The Egyptian god Thoth, who corresponds to the Greek God of Letters, Hermes, and the Roman Messenger of the Gods, Mercurius, is represented as being the author of the forty-two sacred books of the ancient Egyptians. Six of these books were medical, and by them the Pastophor, or embalmer, was guided in his anatomical manipulations on the dead body in process of embalming.

It has been said that the real reason for embalming the dead body with the ancient Egyptians was their belief that the soul would eventually return to it; but I am inclined to think that there was a sanitary object as well, for the embalming was not confined to the human body merely, but to the lower animals, such as bulls, crocodiles, cats, rams, hawks, ibises, etc.

They were a wonderfully "cunning" people, the ancient Egyptians, and more especially the priests, who monopolized the highest grade schools, and plied their knowledge to make the common people work with a will.

There were three ways of embalming practised by the Egyptians; the first and most expensive way was effected as follows:

The brain was carefully and effectually extracted by breaking into the skull through the nose, and in this way the brain was spooned out, and some antiseptic put in its place, generally tar. An oblique opening was made, five or six inches in length, on the left side of the abdomen, a little above the crest of the ileum, and the cadaver was eviscerated by this opening, and the cavity filled with a composition of myrrh, cassia, etc.

The intestines and other internal organs were washed in antiseptics and packed into canopic vases, with aromatics and antiseptic spices. These vases were four in number, and their lids were carved in the shape of the heads of a jackal, a monkey, a human head, and a hawk's head. These were the four genii of the dead, who guarded these special parts of the body put in these vases.

The cadaver was now steeped in natron for seventy days, then washed and swathed in bandages, and was thus handed over to the family. Upward of two thousand five hundred dollars was paid for this process.

The second process was cheaper, and may be described as follows:

A substance called the oil of cedar was forced into the interior of the body through small openings in the thorax and abdomen. This was said to have dissolved, or, rather, dessicated the internal organs, so that they could be removed without mutilating the body.

The body was then steeped in a solution of natron

(native carbonate of soda) till it shrivelled up, when it was taken out, washed, and swathed in bandages.

The third process was inexpensive:

The whole body was simply salted for seventy days, and then given back to the friends.

Manetho, the Egyptian priest and historian, during the reign of Ptolemy Philadelphus, 250 B.C., writes that it was in medicine that ancient Egypt attained any real scientific eminence. According to this author, King Teta, the second king of the First Dynasty, 4000 B.C., wrote treatises on anatomy and surgery, and performed surgical operations with flint flakes. About 3300 B.C., during the reign of Cheops, the builder of the Great Pyramid, a medical papyrus was found by a priest in a temple, and one of the prescriptions in it was as follows:

"Sing a religious hymn. Then say a magical text," in order to drive away a disease or evil spirit.

When medicine was taken to cure a disease, an incantation or formula was said, at the time of taking it, that the drug might do its work swiftly and well.

This medical work is mentioned in the Berlin Papyrus as having been first composed in the reign of "Sent," a king of the Second Dynasty, 3600 B.C.

The oldest medical papyrus we now possess does not go back beyond the Eighteenth Dynasty, 1600 B.C. By that time medicine was already in as advanced a state as in the time of Galenus Claudius, at the end of the second century of our era.

The various diseases known were carefully classified, and their symptoms minutely described, as well as their treatment. The prescriptions recommended in each case were made out in precisely the same way as the prescriptions of modern doctors. One of these was derived from a famous Shemitic oculist of Byblos, near Mount Lebanon, but the greater part belonged to earlier Egyptian medical men who flourished under the first dynasties.

The preparations used were of four kinds: Draughts, blisters, powders, and clysters, minerals as well as vegetables being employed in their composition.

According to this papyrus, which is called Ebers' Medical Papyrus, there were more than twenty different kinds of eye diseases.

Progress in medical knowledge was checked in the time of the Middle Empire, on account of the rule that new medicines and treatment were adopted by the doctor at the risk of being put to death if the patient died.

In the writings of Moses (1500 B.C.) the priests were the physicians, and their treatment mainly aimed at promoting cleanliness and preventing contagion.

In his time we read of Pharaoh having a personal interview with two Hebrew midwives, who must have been very celebrated in their day, to account for their names having been handed down to us in Holy Writ; and if I were to ask Professor Sayre, of New York, why these Hebrew midwives had become so distinguished, I have no doubt he would admit that they had received their instruction originally from the Egyptian midwives, who, long before the Hebrews knew their A, B, C, were not only proficient in what we call, in a popular way, "midwifery," but were specialists in its various departments.

Now, it may be perfectly true, as Professor Sayre stated at the late meeting of the Gynecological Society of New York, that America had given birth to gynecology, but I may be permitted to say, with the darky, that in Egypt gynecology "growed," and has existed there as many years as it has hours in America.

As far as the Egypt of the present day, however, is concerned, I must confess that its gynecology has not advanced in proficiency with its advanced years, but a laudable attempt is now being made to infuse European, not to say American, gynecological knowledge into the native hakimat (doctress), and we hope in time to reflect back on the Occident a brighter light than we have derived from it. In the meantime we ask for the moral support and encouragement of the medical profession in our work out there, where official and political obstacles are thrown in the way of every attempt made to advance the medical department.

In the latter days of Egyptian history, magical formulæ and exorcisms began to take the place of the older prescriptions. Diseases were referred to the malignity of evil spirits, and the priest and sorcerer superseded the physician.

A Demotic papyrus at Leyden is almost wholly occupied with charms—especially with love philters.

In the Twentieth Dynasty, about 1400 B.C., when Rameses XII. was in Mesopotamia, a country that had been conquered by Egypt, the chief of the land of Bakhtan brought to his Majesty his beautiful daughter, with whom Rameses was charmed so that he married her, and called her Ra-neferoo (the most gracious of Ra). The name thus given her indicated how he was enamoured of her.

After Rameses returned to Thebes, in Egypt, and had been there some time, ambassadors came from Bakhtan to beg Rameses to send someone to heal Rint-rash, the little sister of Ra-neferoo, who had an evil movement in her legs.

Rameses ordered all those learned in mysteries to appear before him, and he chose from among them Tahuti-emheb, a royal scribe, who was intelligent and skilled with his fingers (massage); and so this doctor was sent to Mesopotamia to the chief of Bakhtan to heal his daughter. When he reached his patient he found her under the influence of evil spirits that his massage and medicine could not control, so he sent word back to Egypt to have a god sent to exorcise the devils.

Rameses sent an image of the god Khonsu (the war-god of the Egyptians), which was received with great pomp in Bakhtan.

The cure was immediate (faith-cure or mind-cure), and the god Khonsu was installed in the city of Bakhtan. How many further cures he effected is not related, but I can imagine that pilgrimages from far and wide would trudge frequently to Bakhtan to experience the healing power of this image.

We now come to the Greek historical period, dating from about 900 B.C. Hesiod and Homer appear on the scene. Herodotus, who wrote about 450 B.C., tells us that Hesiod preceded Homer; and these celebrities both manifest a considerable knowledge of Egyptian learning, and the medical terms used by Homer became classical words in the history of medicine.

Hecateus, the son of Hegesander, who flourished about 560 B.C., dwelt a long time in Egypt as a student; but how much these Greeks learned in Egypt we can only guess, as they were great plagiarists, and therefore wished to palm off on the Greek world Egyptian learning as if it were their own.

Herodotus, however, is so far honest as to tell us that he had a high opinion of the Egyptians. He says that not only were things better managed in Egypt than in Greece, but Greece had even to go there for its theology, and, he might have added, for its medicine also.

Following up the medical line, we now come to speak of Hippocrates, who is considered to be the father of medicine. He flourished about 480 B.C. He also owed much to Egyptian medicine; and his system of the practice of medicine was said to have been expectant, and would correspond to the homœopathic creed of the present day. He was very strict on diet and regimen, but was often blamed for letting his patients die through doing nothing to keep them alive.

He recommended trephining the skull in injuries of the head, and through his mentioning succussion in connection with fluid in the thorax, our modern auscultation was discovered by Laënnec.[1]

The history of medicine after this is more or less Greek, Roman, and Arab, which need not be touched on here. I may, however, say that after having acquired

[1] Laënnec: René Théodore Hyacinthe, 1781–1826.

a general knowledge of medicine and surgery, the ancient Egyptian medical men took up specialties.

Cyrus and Darius, Kings of Persia, about 500 B.C., sent to Egypt for physicians. The former was afflicted with a nasal polypus, and the latter with ophthalmia. So a rhinologist was sent in the one case and an oculist in the other.

Circumcision was common among the Egyptians in the Fourth Dynasty, 3300 B.C., and probably existed among them much earlier.

Herodotus considered that the Egyptians were the originators of this rite, and that it spread from them to other places. I believe myself that it originated among primitive people independently of one another, and more as a sanitary precaution than for any religious purpose.

The prepuce seems to me to be an unnecessary and dangerous appendage when cleanliness is neglected. I have seen some frightful conditions produced by a neglected prepuce. Its only use seems to me to serve as an analogue, and can therefore be very easily and, in many cases, very advantageously dispensed with.

Circumcision can be traced from China to the Cape of Good Hope. It is practised in the South Sea Islands, in the West Indies, and in Mexico; also among some of the tribes in South America.

Herodotus asserts that the Hebrews and Phœnicians, the Ethiopians, the Kolkhians, the Makronians, and the Hittites, to which Josephus adds the Arabs, learned the rite of circumcision from the Egyptians.

Among the Jews this rite is performed on the child when he is eight days old; and if the eighth day happens to be Sabbath, it has to give place for this rite to be performed, which shows what an important place it has in the Jewish religion.

Among the Arabs, on the other hand, it is generally performed on the child when thirteen years of age, this having been the age of Ishmael, their progenitor, when he was circumcised.

The Kaffirs perform this rite still later in life.

Circumcision is also practised among the Christian Copts and Abyssinians, and that, strange to say, both in the male and female.

The Egyptians considered the Greeks unclean, not merely because they killed the cow, but because they ate swine's flesh and did not practise circumcision.

Abortion Methods at Atlanta.—The *Atlanta Medical and Surgical Journal* gives the following as the recital of what a woman went through who tried to produce upon herself an abortion. She tells the story to her physician.

"I have used two pounds of chloroform in forty-eight hours, and six ounces of ergot in as many hours, besides quantities of balsam-apple, gossypium, turpentine, hot water by injection, and purged and starved myself for weeks, besides resorting to the most violent methods for relief. I have repeatedly jumped or let myself fall from my veranda; I have gone to my kitchen, taken the rolling-pin, and beaten my stomach until tender. I have gone to my cellar, lain down on my back, and rolled a full barrel of unslacked lime up and down my belly. I have leaned over with my full weight upon my piazza-railing time and again, swinging to and fro like a sack. I have run full force against my wood pile. I have——"

"My God! my dear woman, stop; that is enough."

"No, this is not all. Will you hear me through?"

"Yes, madam; proceed."

"I have lived in a room saturated with turpentine and other vile odors; drunk laudanum, eaten opium, and taken morphine with the desperate hope of killing myself. I have gone to the country, mounted the hardest trotting-horses, and ridden them at a mad gallop over the roughest places."

THE RADICAL CURE OF VARICOCELE.

By E. L. KEYES, M.D.,

NEW YORK.

I have been engaged for more than three years past in a continuous effort to perfect the operation for the radical cure of varicocele, and to simplify it. My efforts have been made known, and the stages of progress set forth, in two articles in The Medical Record (February 20, 1886, and September 18, 1886), in which articles the use of various needles has been advocated. I have not changed the method materially, and still find it most simple to do what I suppose every one, from all time, has done who has used a straight needle in a handle—namely, transfix from before backward, partly withdraw the empty needle, carry it to the other side of the veins, and again cause it to emerge at the point of original posterior puncture. I sometimes tie all the veins found large, passing one ligature to the outer side of the vas deferens, one on its inner side, at the same sitting, thus seeming to include the entire cord except the vas deferens. I have never seen atrophy or other evil result follow this very thorough ligation.

The point upon which I lay great stress is thorough antiseptic external irrigation, and the forcible tearing away of the dartos from the point of posterior puncture by violent traction upon the silk while the scrotum is held firm.

I use only very large twisted silk at the present date, and I prepare it simply by boiling it and then placing it in a bottle containing common alcohol. At the moment of operation I dip it and the needle in a bichloride solution in water, 1 to 1,000. I have no doubt hot water would do as well. I tie with all my strength with silk I cannot break. I have known the operation to fail in other hands for lack of using enough muscle in making the first knot. Other points in detail of the operation need not be described. They are most simple, and fully set forth in the articles already alluded to.

I have ceased counting my operations, which must number now near or more than fifty. I have never seen a drop of pus. My first operations with catgut were failures. One gentleman wrote me that a little pus formed in his scrotum after the use of catgut. I did not see it. It was long after the operation, and he was in a neighboring city.

In another case the attending physician informed me that a number of drops of bloody serum oozed for a day or two from one of the punctures.

I have inspected cases many months after the silk had been applied, and still been able to feel the little lump, very small and insensitive, about the veins. Whether the silk is absorbed finally, or remains encapsulated, I do not know. I have never seen an operation fail of success since I began to use silk, now more than eighteen months ago. My last case remained in his room only two days and a half.

But the above statements are only incidental; my object in writing the present note is to introduce to the profession what I consider to be a perfect needle for the performance of this operation. I have used all others in the market, and constructed half a dozen myself. All are defective save the one I now present, and that, I believe, is perfect for its purpose. It is constructed upon the plan of the Reverdin needle—that is, the eye is made to open and shut by a mechanism in the handle.

Last winter, Dr. Magnin had a curved Reverdin needle, and my attention was called to it by Dr. S. Alexander. I had one made straight by Mr. Ford, and tried it, but disliked it because the eye would sometimes open during the manipulations of the point within the scrotum—and the slit would catch a bit of connective tissue, an accident which absolutely interfered with all future subcutaneous work. It therefore occurred to me to have a spring fitted which would keep the eye constantly shut. This has perfected the instrument, and Mr. Ford has

made the parts so that they may all be taken out and dried after each use of the instrument, by simply moving back the band upon the handle and lifting out the plate which covers the spring. The needle is introduced charged with silk, the eye is opened, and the silk taken out; the eye closes itself by the spring; then the naked needle is passed around the vessels and emerges at the posterior puncture. The eye is opened, and the silk slipped in; the eye shuts itself, and the charged needle is rapidly withdrawn. The figures represent the needle and its component parts, the latter displayed on a little larger scale than the former.

Fig. 1 represents the entire needle, with the button on the handle by which the eye is opened. Fig. 2

Fig. 1.

represents: *A*, the slender shaft, with the button upon it by which the eye is opened; *B* is the plate (held upon the handle of the needle by the sliding band) which keeps in *C*, the spiral spring and catch, which, acting

THE SEAT OF STRICTURE.

Dr. T. M. Calnek, of this city, writes: "In dilating the urethra for the relief of stricture, after injecting it with cocaine, I have invariably found that the patient complains of considerable discomfort, and oftentimes of much pain, as soon as the point of the sound enters the stricture. To obviate this, I have had made the following instrument: An ordinary Van Buren sound is perforated throughout its entire length by a very small bore,

OF CANCER OF THE LARYNX.

By CLINTON WAGNER, M.D.,

SENIOR SURGEON TO METROPOLITAN THROAT HOSPITAL, NEW YORK.

In view of the interest that is manifested in the case of the Crown Prince, I have prepared the following brief statement of the results of surgical treatment in six cases of cancer of the larynx, from the statistics of the Metropolitan Throat Hospital.

In two cases the disease had advanced too far for radical treatment. Tracheotomy was performed to prevent sudden death from asphyxia, which seemed imminent. They survived the operation several months.

In one case the disease was confined to the epiglottis. A sub-hyoidean incision was made, through which the epiglottis was removed. The disease recurred within a brief period, attacking the pharynx, base of the tongue, and larynx; the patient survived the operation eight months.

In three other cases tracheotomy and thyreotomy were performed, and the tumors thoroughly eradicated, so far as we could determine; the galvano-cautery and other agents were employed.

In all the cases the disease recurred. In the first case the larynx was reopened several times, at intervals of four or five months, and temporary relief was given by the removal of the growth, which had invaded the pharynx, and also the trachea, around and even below the cannula. The life of this patient was prolonged for two years after the introduction of the cannula.

In the second case, upon the recurrence of the growth, the entire right half of the larynx was removed. He lived eight months after the introduction of the cannula.

In the third case death occurred three months after the operations of tracheotomy and thyreotomy.

The operation of thyreotomy is not of especial danger to the life of the patient.

I have performed it, in connection with tracheotomy, for the removal of benign growths, in three children, aged respectively three, three and a half, and six years. All recovered, with excellent voice. Two of them I have seen within a few days. One was operated on nearly nine years ago, and the other over four years ago.

It is by no means an easy matter to determine in some cases the true character of an intra-laryngeal growth; the microscope, which should be our main reliance, sometimes fails us, and it may be wholly at variance with the clinical history of the case.

In one of the cases above referred to, I submitted portions of the tumor removed to three experts in microscopy. One pronounced it a "small round-cell sarcoma," another declared it to be an "ordinary simple papilloma," while the third maintained that it was an "epithelioma-papilloma."

I have operated over fifty times for the removal of intra-laryngeal growths, and, with one exception, I have never known recurrence of a *benign growth* to take place. The exception was the case in which I removed the entire right half of the larynx. Dr. Heitzman, to whom portions of the growth had been submitted for microscopic examination, reported it to be a papilloma on a "highly inflamed base." He prognosticated correctly, that if recurrence took place, it would be in the form of epithelioma.

ANTIPYRINE IN INSOMNIA.

Dr. Forrest W. Brayton, of Carey, O., writes: "That antipyrine has proved a valuable agent in the treatment of many functional nervous disorders, I believe no one who has had any experience with the drug will deny. Particularly is it of value in the neuralgias and spasmodic affections occurring in those persons who cannot take opium or any of its alkaloids in any form. But it is not only in the reduction of temperature and the relief of pain that antipyrine is of so much service. In insomnia it often gives refreshing sleep after failure with the usual remedies. As an illustration of its action in these cases, I will cite the following:

"Mrs. H——, aged thirty-six, of neurotic temperament, fairly developed and poorly nourished, was delivered of her second child, male, on the morning of October 11, 1887, after a trying labor of twelve hours. The child was large, full ten pounds in weight, and following his birth the uterus was inclined to be relaxed, and more than the usual amount of hemorrhage occurred. She was at once given ergot; in twenty minutes the placenta was delivered, and all hemorrhage ceased. Being a very delicate woman, she was quite reduced and very irritable after this trying labor. She continued irritable and wakeful for five days and nights, notwithstanding the administration of chloral, the bromides, and morphine, hypodermically, which I learned she could not tolerate in one-twentieth grain doses. On the sixth day she had the first elevation of temperature, 100½°; pulse accelerated, 96; the lochia became offensive; there was marked tenderness of the abdomen in the region over the uterus, and at times the patient perspired very freely. During the past six days she had not slept, all told, two hours; her mind wandered; she was sometimes crying, at others laughing, at no time quiet. At this time, at the suggestion of my father, Dr. A. Brayton, I gave her antipyrine along with antifebrine, six grains of the former and two of the latter. She soon became quiet, and in an hour was sleeping soundly. This continued six hours, at the expiration of which time she awoke much refreshed. I should mention that vaginal injections of a bichloride solution, 1 to 2,000, were given every eight hours. The antipyrine was given the four nights following, each time producing refreshing sleep. The temperature soon fell to normal, the lochia became natural, and the patient was convalescent at the end of the second week. I should have mentioned the fact that

quinine in tonic doses was given all through the second week. In this instance the antipyrine was given in connection with antifebrine, a combination which my father prefers. I usually administer the antipyrine alone, giving never less than ten, or more than twenty, grains, to an adult at one dose. As I am not aware that anyone has made use of this drug in insomnia, I have thought proper to make mention of our experience with the drug in these cases. Though I have no experience with antipyrine in puerperal convulsions, I believe it will be found of great benefit in preventing them. I would suggest its use in these cases, and will give it a practical application the first opportunity afforded me."

AN UNUSUAL CASE OF CROUP.

Dr. Edward Gray, of Benicia, Cal., reports the following case: "N. D——, aged nine years, fell ill on September 27th, and was found to be affected with pharyngeal diphtheria. Twelve days before, a younger brother had died of this disease under symptoms of laryngeal stenosis. This boy was under the care of another practitioner, who had one morning appointed two o'clock of that afternoon for a consultation with me, but the child had suddenly died before the appointed hour. No epidemic of diphtheria was in the town, but there had been two other sporadic cases. The faucial symptoms were well marked, and the constitutional symptoms of moderate degree—a little swelling of the glands at the angle of the jaw and a mild fever. But on the third day there appeared plain evidences of involvement of the larynx—namely, a considerable degree of hoarseness of the voice, and a croupy cough, with a certain amount of dyspnœa. The natural supposition was that there was exudation in the larynx, and the condition of the child was thought to be one of great danger. With the view of obtaining information as to the need of an early tracheotomy, and in the desire to observe the visible characteristics of a laryngeal membrane, I now examined my docile little patient with the laryngoscope, and was surprised to find not the trace of a membrane in the larynx! The signs were those of a marked catarrhal laryngitis. Use was made of the laryngoscope for some days longer, but no membrane was deposited, and, meanwhile, that in the fauces was cleared away. The child promptly recovered without sequelæ, and is alive and well now, two years afterward. It is apparent how in this case a claim might easily have been made of recovery from diphtheritic croup, had not resort been had to the laryngoscope; and further, that the use of this instrument yielded knowledge which justified a more favorable prognosis than could otherwise have been given Without the laryngoscope, how can we tell what percentage there may be of this rare combination of diphtheria and simple laryngitis?"

Dr. Gray then cites a number of references from J. Lewis Smith, Watson, Flint, and Gay, showing that suffocative symptoms occurring in the course of pharyngeal diphtheria are, in the opinion of these writers, almost always due to extension of the membrane to the larynx.

"The interest of the foregoing case, therefore, lies in its being an exception to an established rule. To the importance of the exception, as regards prognosis, attention has already been directed."

BORACIC ACID IN GONORRHŒA.

Dr. W. C. Abaly, of Madison, Wis., writes: "My experience with boracic acid and glycerine, in the treatment of subacute and chronic gonorrhœa, has been so successful for the past year that I can confidently say it is almost a specific; I have used it in thirty cases, and only in three did it fail. One of them was a heavy drinker of spirituous liquors, and the other two had strictures which it was necessary to treat in the usual way before the discharge ceased. The mode in which I use the acid and glycerine is as follows: I prepare about two drachms at a time, which is sufficient for one séance, using half a drachm boracic acid and one and a half drachm glycerine: then, by the use of a soft rubber catheter of proper size—one which will pass easily the full length of the urethra—and a hard rubber syringe, with a nozzle of large enough calibre to allow the paste to flow freely, I commence injecting from the prostatic urethra, gradually withdrawing the syringe and stripping the catheter with thumb and forefinger, until the full length of the urethra has been thoroughly saturated. This is to be repeated every second day. I always have patient urinate before using the treatment, or, what I sometimes do in case of a new case, to locate the prostatic portion, is to allow the catheter to pass into the bladder, allowing the urine to come away, then withdraw and use the acid and glycerine injection. The desire to urinate is quite urgent for a few minutes, but soon passes off. In some few cases, in order to avoid urination, and the dislodgement of the paste thereby, I have the patient immerse the full length of the penis in cold water, which always lessens the desire."

SLOW HEART-BEAT.

Dr. G. W. Squire, of East Avon, N. Y., reports the

away of the dartos from the point of posterior puncture by violent traction upon the silk while the scrotum is held firm.

I use only very large twisted silk at the present date, and I prepare it simply by boiling it and then placing it in a bottle containing common alcohol. At the moment of operation I dip it and the needle in a bichloride solution in water, 1 to 1,000. I have no doubt hot water would do as well. I tie with all my strength with

COCAINE AS AN ANTI-EMETIC IN YELLOW FEVER.

Dr. J. E. Jennings, of Aspinwall, sends the following communication: "As is well known, vomiting is one of the most constant symptoms of yellow fever. Occurring early, it marks the whole history of the disease, and in most severe cases gradually becomes more persistent until the characteristic 'black vomit' appears. All writers on the subject agree in the statement that the 'black vomit' is a very grave symptom; hence any drug that can prevent or check this symptom would aid us very much in the treatment of this truly terrible disease. Lime-water and milk, small pieces of cracked ice, iced champagne, lime-juice, carbolic acid, pepsin, ingluvin, external applications, etc., seem to exert a favorable influence upon the vomiting, but up to the present moment no remedy has been brought to the notice of the profession that could be regarded as anything like a positive anti-emetic in this disease. Knowing the power of cocaine as a local anæsthetic, Dr. Thorington, physician for the Panama Railroad, and myself resolved to test its value as an anti-emetic in yellow fever.

"The following cases illustrate very happily the results we have obtained from the use of this drug:

"Case I.—Miss L——, Spanish, aged twenty-three, arrived in Aspinwall from Spain four months ago. When called in to see patient, she was found to be in the second stage of yellow fever. The following day 'black vomit' appeared, for which we ordered ten minims of a four per cent. solution of cocaine to be given with a little water every hour. The effect of the medicine was at once apparent, and after the second dose all vomiting ceased. Patient recovered.

"Case II.—Miss H——, Spanish, aged nineteen. Has been living in this city for the past seven months. This patient was thought by the family to be suffering from malarial fever, until the fourth day, when her disease was recognized by the appearance of black vomit. At this time cocaine was administered as in Case I., with like success.

"Case III.—Mr. S——, American, aged forty-nine. Two months after his arrival in this city he was taken sick with yellow fever of a very severe type. Black vomit appeared at the end of the first twenty-four hours, but was at once checked by the administration of small doses of cocaine. In this case it was noticed that a considerable quantity of coagulated blood was passed from the bowels. Patient died on the fourth day, there being complete suppression of urine.

"Case IV.—Captain N——, Welshman, aged forty-five. Was taken sick with yellow fever while his vessel was discharging coal in this port. Had copious black vomit on the third day, which was controlled by cocaine. Patient recovered.

"In the above cases from two to five doses were all that were necessary to control the vomiting. The patients rested easier and seemed to relish the nourishment given them. At the same time it was noticed that the cocaine acted as a diuretic; under its influence the quantity of urine passed was somewhat increased."

AN URETHRAL SOUND ADAPTED TO THE DIRECT APPLICATION OF COCAINE TO THE SEAT OF STRICTURE.

Dr. T. M. Calnek, of this city, writes: "In dilating the urethra for the relief of stricture, after injecting it with cocaine, I have invariably found that the patient complains of considerable discomfort, and oftentimes of much pain, as soon as the point of the sound enters the stricture. To obviate this, I have had made the following instrument: An ordinary Van Buren sound is perforated throughout its entire length by a very small bore, and to the proximal end is attached a syringe such as is commonly used with the hypodermic needle. The urethra is first injected with a solution of cocaine, which is held in the canal by the patient for about three minutes. The syringe is filled with either a solution, or with the oleate, of cocaine, attached to the sound, which is then filled from the syringe, and is ready for use. As soon as the patient complains of pain a slight pressure on the piston, made by the forefinger, forces out a drop or more of the contained anæsthetic, the instrument being firmly held in place for one or two minutes. In every case in which I have used the sound so arranged it has passed readily, without any discomfort to the patient, and without the slightest constitutional disturbance.

"I claim no new idea—Bumstead's, Guyon's, and all other deep urethral syringes are on the same principle—but believe that the day is not distant when, by means of cocaine applied in some such manner as this, even the worst cases of urethral stricture will be safely, painlessly, and effectually cured without recourse to urethrotomy, divulsion, or cutting operations."

SPONTANEOUS DELIVERY IN A CASE OF PLACENTA PRÆVIA.

Dr. C. W. Reeder, of Portsmouth, O., relates the following: A woman, aged thirty-five, the mother of seven children, in the fifth month of pregnancy began to have hemorrhages, which recurred at intervals for eight weeks. At this time a severe flooding took place, and irregular and weak labor-pains were felt. After she had fainted several times Dr. Reeder was sent for, but did not arrive until three hours later, when he found that the child had been born two hours before. The woman was comfortable, though pale and weak, with a pulse of 120. The child had been born with the membranes intact, the placenta coming first, according to the testimony of a neighbor, who was the only one with the patient at the time. This woman, at the time she sent for Dr. Reeder, had given the patient two saucerfuls of tansy-tea, with the result of an increase in the pains, diminution of the hemorrhage, and expulsion of the child soon after.

Progress of Medical Science.

A Plea for Suprapubic Lithotomy.—Dr. Svensson, of Stockholm, having practised all the recognized methods of operating for stone in the bladder, has had complete success since he commenced to perform the suprapubic operation for large stones, and in severe and complicated cases (*The British Medical Journal*). He has performed this operation with various objects, and he considers it by no means dangerous in itself if it is only executed with the necessary precautions (in two sittings, with antiseptic methods, a cautious injection into the bladder, etc.). Thus he removed by suprapubic lithotomy, or epicystotomy, as he terms it, a stone nearly as large as a hen's egg, from an old man who was extremely weak, and who was suffering at the time from senile gangrene affecting the foot and the lower part of the leg. A few weeks later, amputation had to be performed through the thigh; but the patient was afterward sent to his home (which was at a considerable distance) completely cured. Dr. Svensson does not invariably perform the operation in two sittings, and he does not resort to it, of course, in all cases of stone. Lithotrity at a single sitting, litholapaxy, as well as median lithotomy, always, he considers, present their own indications, which is not the case with the lateral operation. In the performance of suprapubic section he agrees with Petersen that plugging the rectum, while at the same time the bladder is filled, contributes in a marked degree to facilitate the operation and to render it free from danger. Complete suture of the wound is not generally desirable, but the application of some sutures to the bladder serves to check posterior hemorrhage, and may be requisite for this purpose. Usually before opening the bladder Dr. Svensson passes a running noose of thread through the wall of the bladder, so as to include the line of incision, thus providing a remedy in case hemorrhage should occur. His experience is that posterior hemorrhage occurs in an eighth of the cases if sutures are not applied to the wound in the bladder. He endeavors to show that the suprapubic operation is safer than other methods, the patient recovering more rapidly than after litholapaxy, the pain also being very slight. An additional advantage is on the side of suprapubic section: it is available for other affections of the urinary passages, and without it some of these diseases would be incurable. He hopes in a subsequent paper to give an account of his experience in the Sabbatsberg Hospital.

equally successful [illegible] mended for applications to the face, and ichthyol soap for the scalp. Nussbaum considers ichthyol a reducing agent—*i.e.*, as acting on the cocci by making the soil where they multiply unfit for their nutrition. He does not regard it as an antiseptic.

Tape-worm and Pernicious Anæmia.—Last year Professor Runeberg advanced the view that pernicious anæmia, in some cases at least, was dependent on the [illegible] of the intestinal tape-worm [illegible]

The Toxic Power of Non-febrile Pathological Urine.—Dr. Feltz has already shown that the toxic properties of febrile urine are far greater than those of non-febrile urine, but that this fact is not due to the density of febrile urine. He has recently made a series of experiments upon the noxious effect of non-febrile urine from patients suffering from glycosuria, albuminuria, icterus, cancerous cachexia, and anæmia. The urine used was fresh, filtered, summarily analyzed, and heated to the temperature of the dog's body before being injected. Intravenous injections were practised according to the method of the author and M. Ritter. These experiments showed that glycosuric urine from non-cachetic patients is not more toxic than normal urine. Icterous urine from cases of organic disease of the liver, albuminous urine from cases of serious renal disorder, and urine from patients suffering from cancerous cachexia or anæmia, is considerably more toxic than normal urine. The

symptoms observed during the experiments, the kind of death which followed, the conditions found at the *post-mortem* examination, which the author terms uræmic accidents, are similar to those observed when normal urine is injected in sufficient quantities to cause death. The author concludes from this that it is the increase of the noxious principles contained in normal urine, rather than the presence of new noxious principles, that determines the degree of toxicity of pathological urine, and that the salts of potassium contained in urine are the principal agents of uræmic intoxication.—*La France Médicale.*

Retro-rectal Dermoid Cyst.—Biernacki describes a case (*The British Medical Journal*) of this kind which occurred in Professor Gusserow's ward. A retro-rectal tumor was diagnosed, and during labor its nature was made evident by tapping, whereby nearly a pint and a half of hair and greasy material escaped. Notwithstanding the consequent diminution in bulk of the growth, it still remained such an impediment to labor that perforation was necessary. Convalescence was retarded by suppuration of the cavity of the cyst. Notwithstanding free incisions, pus with a fecal odor burrowed beyond the limits of the growth, under the right labium majus, the nates, and the vagina. After two months the patient was discharged cured. Biernacki has found records of four other cases of retro-rectal dermoid cyst.

Dermatoses from Emotion.—Dr. Leloir gives the following characteristics of the emotional dermatoses: Rapid onset after the moral shock, and, should the dermatosis not immediately succeed the shock, a series of nervous troubles, such as pruritus and neuralgia, precedes the cutaneous eruption. The progress is rapid, and the lesion soon attains its maximum development. The affection is always superficial, scarcely ever involving the deeper part of the skin, and being chiefly of the vaso-motor, catarrhal, or pigmentary sort. Excessive pruritus is a feature of these dermatoses. Their duration is relatively short, and they are especially to be observed in females.—*Journal de Médecine de Bruxelles.*

Cold Affusion in Apparent Death from Lightning.—Dr. Hidalgo, of Mexico, brought before the Academy of Medicine of that city, at a recent meeting, the case of a man who had been struck by lightning, and was at first thought to be dead, but who, after having had, at the suggestion of a passer-by, a large quantity of cold water thrown over him, began to show signs of vitality. He [illegible] laryngoscope, and further, that the use of this instrument yielded knowledge which justified a more favorable prognosis than could otherwise have been given. Without the laryngoscope, how can we tell what percentage there may be of this rare combination of diphtheria and simple laryngitis?"

Dr. Gray then cites a number of references from J. Lewis Smith, Watson, Flint, and Gay, showing that suffocative symptoms occurring in the course of pharyngeal diphtheria are, in the opinion of these writers, almost always due to the membrane. [illegible] time that he had something the matter at another that he had rheumatism all over, but he made no reference to the lightning. Dr. Hidalgo saw him the next day and found him in a semicomatose state. The pulse was 75, full and compressible, the temperature normal, and the respiration rather rapid. He was so deaf that he could only be made to open his eyes by shouting close to his ear. The pupils were contracted. He complained of pain all over, but especially in the head and arms. He had passed three badly smelling liquid stools during the night. He was neither hungry nor thirsty. The electric spark had entered the upper part of the right parietal region, just behind the auricle. The scalp was burned over a surface of several inches, and a spot of dried blood was seen on the upper part of the auricle. The right side of the neck was reddened as by a burn of the first degree; below this, as far as the umbilicus, the effects were equal to those of a burn of the second degree. The electric fluid had passed down the inner aspect of the right leg, producing a burn of the second degree. It had then passed down to the foot, where the burn was of the first degree, and the strip of skin affected much narrower than above. The hat, coat, and trousers were injured—as if torn—along the course of the current, but they were not burnt in any part. The patient was treated with sedatives and some clysters, and in sixteen days was perfectly well. Dr. Hidalgo supposes that the pneumogastric was affected by the shock, which paralyzed respiration, and subsequently the heart's action, similarly to the behavior of an overdose of chloroform. The indication, therefore, was to re-establish respiration, and this was admirably fulfilled by the cold affusion, which, fortunately, was administered quickly, before the paralysis of the heart had become absolute.—*The Lancet.*

The Presystolic Murmur, falsely so called.—From a study of the so-called presystolic murmur Dr. Dickinson (*The Lancet*, October 8, 1887) maintains that he has demonstrated that the murmur occurs with the systole, not before it. Systole refers not to a sound, but denotes a contraction. He says, in conclusion, that if anyone is pleased still to call the murmur presystolic, let him do so, so long as he makes it clear to all that he speaks not of the systole, but of the systolic sound. "But if my contention be just, it will be best to avoid a term the use of which must involve an error either in observation or language. The point of practical importance is that the murmur does not belong to the systole of the auricle, but to that of the ventricle, and is therefore that of mitral regurgitation. The difference between this murmur and that of mitral regurgitation, as universally accepted, is chiefly in the modified first sound by which it is concluded, and the evidence thus afforded of the closure of the valve. It may be accepted as a general truth that a diseased mitral valve does not shut unless the orifice is narrowed; thus the so-called presystolic murmur becomes a sign of stenosis. For this great landmark of cardiac diagnosis we have to thank Dr. Gairdner. Our estimation of its value will not be lessened by any difference of opinion as to the precise origin of the morbid melody which we can so readily recognize, and from which we learn so much. Finally, I have endeavored to rehabilitate the old mitral diastolic murmur, and restore it to its proper station as that of mitral obstruction and the auricular systole." If the term presystolic is inappropriate, how is this murmur to be designated? We must call it something to distinguish it from the other regurgitant mitral murmur, the old-fashioned one, which continues through the whole systole and implies a valve that is always open. The "presystolic" might become "early systolic," in regard to its position in the systole, or the "stopped systole," in reference to its abrupt termination; while the other might be spoken of as the "full systolic," being unabbreviated and occupying the whole act. The feeble and infrequent murmur of mitral obstruction, the true auriculo-systolic, may keep its old titles, "direct mitral" and "diastolic mitral."

The Utility of Subcutaneous Injections of Carbolic Acid.—Professor Benedikt has published a paper, on the "Use of Subcutaneous Injections of Carbolic Acid." At the instance of Dr. Kunze, he had tried, about seventeen years ago, injections of a two per cent. solution of carbolic acid in cases of rheumatism of the shoulder, with surprisingly good results. The joint, which was very painful on passive motion before the injection, was found, a few minutes after the injection, to be freely movable, as if it had been narcotized. This result was the more surprising, as it was known that subcutaneous injections of morphine had not so speedy an effect in such cases. In affections of the joints, in which there were great tenderness on pressure and distinct swelling of the bones, the morbid process disappeared in a few days after the injections. This was especially true of recent cases;

but even in old and complicated cases the effect was not merely a passing one, but lasted some time. Professor Benedikt also tried subcutaneous injections of carbolic acid in cases of polyarthritis, and in the first cases which he had observed the success was very striking. When the injection was made in the neighborhood of the affected joint, the pain not only quickly diminished, but the high temperature and the pains in the other joints also decreased. The course of the case was the same as after the administration of large doses of the salicylate of sodium. Both agents had a general and also a local influence, but the cause of the disease was only gradually eliminated from the body, and, in Professor Benedikt's opinion, this elimination was scarcely accelerated so much by the administration of the salicylate of sodium as by subcutaneous injections of carbolic acid. Professor Benedikt, therefore, advocated this plan of treatment in polyarthritis. The evil effects of the salicylate of sodium on the appetite, and in many cases also on the auditory apparatus and the whole organism, were well known. When both modes of treatment were combined, the salicylate of sodium being administered in small doses, and one to three subcutaneous injections of carbolic acid being given in twenty-four hours, the course of the affection was very much accelerated, and no bad consequences were observed, especially if the treatment was carried out from the very beginning of the disease. Extraordinarily good results were obtained by the method in cases of inflammation of the sheaths of tendons, especially after injury. A few injections sufficed to cut short the morbid process, and no local pain or muscular atrophy, etc., was observed, provided the disease was treated in the above-mentioned way from the very first outset. Subcutaneous injections of carbolic acid also gave Professor Benedikt good results in cases of pain due to club-foot, as well as in local periosteal inflammation, in spondylitis, and in scrivener's palsy. In most cases he had given only one injection a day, but in cases of polyarthritis he had given from three to five injections in the course of twenty-four hours. The local anæsthesia which occurred in two cases (lasting in one of them for several months) was due to the effect which the fluid exerted directly on cutaneous nerve-trunks.—*Vienna Cor. British Medical Journal.*

THE VOMITING CENTRE.—Professor Tumas, who has been making a series of researches on the subject of

[illegible] OF THE INTERNATIONAL MEDICAL CONGRESS.

AN esteemed correspondent, living in Georgia, writes us protesting against the announced intention of the committee having the matter in charge to print the papers read before the International Medical Congress at Washington in the language in which they were written and delivered. He urges that if such a course be followed the "Transactions" will be a sealed book to nine-tenths of the physicians of this country, and the papers therein contained will be to them as if they had never been written.

There is much truth in what our correspondent says, and we can readily appreciate his reasons for objecting

THE CAUSE OF MORNING SICKNESS DURING PREGNANCY.—Many theories have been adduced regarding the cause of morning sickness during pregnancy. All, however, appear to have been too speculative, and no one has met with anything like universal sufferance. Dr. Oliver says (*The British Medical Journal*) that evolution may aid us in arriving at a just and feasible interpretation. From the earliest period of existence every organism has been endowed with two distinct qualifications: 1, that of maintaining self; 2, that of perpetuating its species. At first the double function was performed by a uniform mass, free from any semblance of structural differentiation. Habitual localization of function, however, produces eventually a specialization of structure, and with it the evolution of a nerve-tract, whereby the inter-dependence is maintained. It is therefore feasible to suppose that the nerve-centre which regulates the process of assimilation is either in apposition, or at least in direct communication, with that which presides over the organs of generation. All the visceral functions are now performed automatically, and are regulated by nerve-centres located in the medulla oblongata; the uterine, by inference, being no exception. Considering the close relationship that exists throughout life between the two processes of assimilation and reproduction, there can be no doubt that the representative nerve-centres act and react upon each other. When the uterus becomes the nidus for a developing germinal mass, the molecular disturbances radiated therefrom to the reproductive centre are liable to be transmitted to the pneumogastric as well, and induce either a feeling of nausea or actual emesis. Usually, however, in the course of a few months, through habit, the pneumogastric centre becomes tolerant, and the symptom evidencing disturbance at the same time disappears. It is difficult to understand why the sickness should be experienced more especially in the morning, unless it be that the change from the recumbent to the erect position after sleep renders the whole nervous system more liable to explosive disturbances. Frequently we find patients who only suffer from disturbances associated with epilepsy on assuming the erect position after sleep. The more highly unstable the nervous system is generally, the more likely is a woman who becomes pregnant to suffer markedly and for a lengthened time from sickness, whether matutinal or more or less constant. It is well, however, to remember that the molecular radiations from the uterus itself may, for some reason or other, be materially augmented; and such, acting on a nervous system otherwise apparently healthy, may induce an aggravated train of events.

ICHTHYOL IN ERYSIPELAS.—Nussbaum claims that erysipelas may be quickly healed by the use of ichthyol. The wound attacked by erysipelas is disinfected and covered closely with iodoform gauze. The erysipelatous surface, while still spreading, is painted with ointment made of equal proportions of ichthyol and vaseline. The part thus painted is covered with ten per cent. salicylic lint, and fixed with a gauze bandage. Next day the border is found to have remained stationary, while the inflamed surface is shrunken into yellowish-brown creases, and is painless. After three days the dressing is discontinued. Five consecutive cases treated on this plan gave equally successful results. Ichthyol collodion is recommended for applications to the face, and ichthyol soap for the scalp. Nussbaum considers ichthyol a reducing agent—*i.e.*, as acting on the cocci by making the soil where they multiply unfit for their nutrition. He does not regard it as an antiseptic.

TAPE-WORM AND PERNICIOUS ANÆMIA.—Last year Professor Runeberg advanced the view that pernicious anæmia, in some cases at least, was dependent on the presence of the intestinal tape-worm, bothriocephalus latus. His views were supported by Dr. Reyhen and others, but strongly opposed by Biermer, Quincke, and Immermann. A case which tends to support Runeberg's view has been recorded by Dr. Schapiro (*The Lancet*, October 8, 1887). A lad, thirteen years of age, came under treatment for intense anæmia of a progressive type, characterized by great diminution of red corpuscles and of hæmoglobin, with liability to cutaneous hemorrhage, epistaxis, etc., marked cardio-vascular bruits, pyrexia, and without any emaciation. It was not until the administration of anthelmintics had resulted in the evacuation of a large quantity of segments of bothriocephalus that he began to regain strength and color. His recovery from that date was rapid. The writer attributed the anæmia to the disintegrating action on blood-corpuscles of some chemical product of the parasite which was absorbed into the blood.

CANCER OF THE LARYNX.

WHILE the most frequent form of laryngeal tumor is the papilloma, malignant growths are not so excessively rare as used to be supposed; and of malignant tumors cancer is the most frequent form.

Primary cancer of the larynx occurs most frequently in males, and in those who are between the ages of fifty and sixty. Hereditary influence has not been observed. The exciting causes are not well determined, but the abuse of alcohol and tobacco, residence in cold, damp climates, the inhalation of irritating gases, and injuries to the neck have all seemed to have an influence, especially when combined with violent use of the voice. The assertion that repeated attempts to extract benign tumors by means of forceps tends to make them malignant is not substantiated. But tampering with a malignant tumor may make it worse.

Cancer starts most frequently in the ventricular bands and vocal chords, or in general, in the middle and upper part of the larynx, and it has a curious habit of beginning oftener on the left side.

Cancer of the larynx assumes only two leading types, the epithelioma and the encephaloid. In one hundred and sixty-seven collected cases the disease was epithelioma in one hundred and forty-nine, and encephaloid in eighteen instances.

Cancer of the larynx is preceded often by a hoarseness or huskiness of voice which may last several years, though usually not so long, before more decided symptoms appear. For some time to come, it is probable that nervous people with husky voices will be flocking to physicians in order to be assured that they have no cancer. The voice soon becomes not only husky but very weak. It is, however, not altogether lost till very late in the disease.

After a time difficulty in respiration and in swallowing occurs, the dull pains at first present become sharp and lancinating, and are reflected to the ears, orbit, forehead, and jaws. Cough is usually slight, but expectoration and salivation increase, the breath becomes foul, slight hemorrhages occur which are characteristic of the disease, cachexia sets in, the patient becomes emaciated, his face assumes a yellowish pallor. In constant pain, unable without distress to breathe or swallow, with hope gone and strength failing, the unfortunate patient offers a spectacle of the deepest misery.

The disease lasts rarely over eighteen months, though a few cases are reported in which the patients lived three, four, six, ten, and even fifteen years (Ziemssen). The course is equally rapid in epithelioma and encephaloid. Tracheotomy undoubtedly prolongs life considerably. In Fauvel's cases the patients lived for over two years when tracheotomy was performed. It seems to prolong life more in epithelioma than in encephaloid.

Laryngotomy, in fine, is the surgical operation most useful in cancer of the larynx.

An ingenious modification of laryngectomy has been devised by Drs. Solis Cohen and Martin, which promises better results than those previously obtained. By it the entire respiratory part of the larynx can be removed and the greater part of the thyroid cartilages left to perform their functions as shields and supports. On the whole, however, the outlook for the patient who expects to have the larynx removed is most discouraging. There is barely an even chance that he outlive the week following the operation. If it succeed he can live perhaps one or two, or possibly more years, but mutilated and in anxiety and discomfort.

Laryngotomy is the simpler, safer, and surer operation, though it holds out no hope except for slightly prolonging life.

DIETETICS IN MENTAL DISEASES.

THE question of diet in the treatment of disease is one of the most important subjects with which the therapeutist has to deal, and is one that deserves even more careful study than it has hitherto received. Its importance is generally recognized when one has to do with diseases accompanied by, or dependent upon, lesions of any portion of the digestive tract. It is even understood in a general way that a tonic regimen is essential to the successful management of affections characterized by a lowered state of the system. But it may be said without fear of contradiction that physicians are too little alive to the necessity of recognizing this indication, and are

and the auricular systole." If the term presystolic is inappropriate, how is this murmur to be designated? We must call it something to distinguish it from the other regurgitant mitral murmur, the old-fashioned one, which continues through the whole systole and implies a valve that is always open. The "presystolic" might become "early systolic," in regard to its position in the systole, or the "stopped systole," in reference to its abrupt termination; while the other might be spoken of as the "full systolic," being unabbreviated and occupying the whole act. The feeble and infrequent murmur of mitral obstruction, the true auriculo-systolic, may keep its old titles, "direct mitral" and "diastolic mitral."

THE UTILITY OF SUBCUTANEOUS INJECTIONS OF CARBOLIC ACID.—Professor Benedikt has published a paper, ject into three main classes of cases, viz., melancholia, mania, and dementia, or states of mental depression, exaltation, and weakness, respectively, and he shows that in all these three classes the necessity exists of a generous diet.

In melancholia, the author says, there is often a profound disturbance of nutrition in patients whose brains, by inherited or acquired defect, are the weakest organs in the economy, and are, therefore, the first to give evidence of functional derangement. The conditions present in acute melancholia are "suppressed secretions, consti-

pation, coated tongue, foul breath, loss of appetite, or actual sitophobia, feeble circulation, superficial respiration, and constant loss of weight." The physician, he says, frequently "fails to recognize in the pasty tongue and saburral condition of the 'primæ viæ,' and in constipation due to atony of intestinal muscles, the local signs of general malnutrition, and to understand that they often disappear under a generous diet."

In mania, also, although the conditions are here widely different, the indications for a full and nourishing diet are none the less imperative. Although the amount of food ingested is large, yet the metabolic changes are rapid, and, by reason of the constant movement and consequent expenditure of muscular energy, the waste of tissue is very great. The physiological ration of food is here insufficient, and overfeeding becomes necessary, if cortical atrophy and secondary incurable dementia are to be avoided.

In dementia, finally, still another condition exists. "Digestion is performed with mechanical regularity, and the patient grows fat. Bodily waste and repair finally become equal, and the patient may maintain this equilibrium for years together. If there ever be a time in the history of these cases for the practice of an economical diet, it is during this final stage. A minimum of proteid food, with a good share of the cheaper fats and carbohydrates, suffices to keep these demented creatures in comparative physical well-being." The author insists, however, with much reason, that the diet, even in these apparently hopeless cases, should be maintained at a generous standard, for hope of recovery should be abandoned only when death has come, as the writer has witnessed instances of restoration to reason after the lapse of twenty years. In the article referred to, Dr. Kellogg specifies the amount and kind of food required in each of the different classes of mental states into which the cases are divided.

THE TRANSACTIONS OF THE INTERNATIONAL MEDICAL CONGRESS.

An esteemed correspondent, living in Georgia, writes us protesting against the announced intention of the committee having the matter in charge to print the papers read before the International Medical Congress at Washington in the language in which they were written and delivered. He urges that if such a course be followed the "Transactions" will be a sealed book to nine-tenths or ninety-nine twentieths of the physicians of this country, and the papers therein contained will be to them as if they had never been written.

There is much truth in what our correspondent says, and we can readily appreciate his reasons for objecting to pay ten dollars for a book a considerable part of which is printed in a language that he does not understand. Yet there are many and great difficulties in the way of publishing an American edition such as he suggests. It would cost a very considerable sum to have translations made of all the French and German articles, to say nothing of the additional expense of printing the papers when translated. We think, too, that he underestimates the linguistic abilities of American physicians, and we question whether one-third of those who receive the "Transactions" will be found unable to read either the French or the German papers, and to many, doubtless, it is no task to read both.

The letter to which we have referred was, however, written before the Congress had been convened, and we doubt not our correspondent's views concerning the absolute necessity of possessing the volume of the transactions have by this time undergone some modification. Those who have received the issues of The Medical Record containing the very complete report of the Congress will have little need of turning to the "Transactions" for the really essential portions of the papers read. Some of the articles, indeed, which were read by title will appear only in the volume of the "Transactions," but they were few in number, and not many of them, to judge by their titles, were of very great importance.

THE OPERATION OF LARYNGECTOMY.

It is now but fourteen years since Billroth removed the whole larynx from a human being. The operation was successful, though the patient died a year later from cancer of the cervical glands. In 1870 Czerny had experimentally investigated the subject, shown the feasibility of the operation upon dogs, and indicated a mode by which an artificial larynx could be inserted, so that certain sounds could be made. Later Gussenbauer devised a most ingenious instrument, which was used by Billroth's patient. Since 1873 the operation of laryngectomy has been done over one hundred times, chiefly by German and Italian surgeons, and in over fifty cases for cancer of the larynx. The results, so far as the operation was concerned, have been fairly good. Over thirty, or about one-third of the cases, have survived for a time (Roswell Park, "Wood's Reference Handbook of the Medical Sciences"). We believe, however, that all subsequently died from a recurrence of the disease.

The two great measures, according to Park, which have enabled modern surgeons to do this operation are the hæmostatic forceps and antiseptic gauze. These have permitted him to work in extremely vascular parts, and to prevent the septic secretions from entering the lung and setting up pneumonia. The artificial larynx devised for these cases is a marvel of ingenuity, though practically it is not usually well tolerated. To Gussenbauer belongs the credit of first devising the most complete form. By means of it the patient may be able, after a time, to swallow without difficulty, and to utter distinct speech. This latter feat is accomplished by inserting a metallic reed like that of a melodeon into the air-current. This vibrates, and the sound is converted by the organs of articulation above into spoken voice. Such speech is, of course, literally monotonous and somewhat weird, but it is speech.

Unilateral laryngectomy has been performed a number of times, over twenty in all, and it is occasionally indicated, because in fifty per cent. of cases cancer of the larynx is unilateral.

The advantage of partial laryngectomy is that it is less dangerous, and that the patient can speak without the help of an instrument. It is indicated according to Lennox Brown in unilateral and intra-laryngeal epithelioma, and in recent non-infiltrating sarcoma. It is useless in pharyngo-laryngeal epithelioma and whenever there is im-

plication of the cervical glands and structures adjoining the larynx.

Laryngectomy, though it has now been so often "successfully" done, is still regarded with doubtful favor by some laryngologists. The results, so far as prolongation of life is concerned, are very poor—probably not over five per cent. outlive the year, while forty-two per cent. die in eight days. By partial laryngectomy much better results have been claimed.

THE RELATION OF ACNE TO DISEASE OF THE NASAL FOSSÆ.

MUCH has been written of late upon the influence of genital irritation in the causation of acne of the nose and face. While, doubtless, the former often stands in a causal relation to the latter, it is difficult to find a satisfactory explanation of its mode of action, and for that reason many regard the alleged connection between the two as fanciful and purely imaginary.

By a curious coincidence, such as is not infrequently observed, two observers—one an American, the other a Frenchman—have, almost simultaneously, called attention to the frequent coexistence of acne of the nose and face and disease of the nasal fossæ. They were both struck by the frequency with which they found these two affections coexisting, and they were thereby led to believe that one might possibly stand in an etiological relation to the other.

In a paper read before the Philadelphia County Medical Society (*Weekly Medical Review*, October 29, 1887), Dr. Carl Seiler related three cases, among others that he had observed, of acne occurring in patients suffering with chronic atrophic rhinitis, and stated that he had come to regard this affection as, in many cases, the exciting cause of acne. He does not reject the theory of a genital or digestive reflex as the predisposing cause of acne, but believes that it alone is seldom sufficient to produce the cutaneous lesion under normal conditions, unless in cases of long duration. A consideration of the various predisposing causes leads to the belief that "an irritation of the nervous system must exist somewhere—be it in the mucous membrane of the stomach or in the sexual apparatus—which, by reflex, acts upon the easily influenced capillary circulation of the skin of the face and neck, and thus, by causing a change in the capillaries around the sebaceous glands, causes a perverted action of these glands if it is kept up for any length of time, or if no relief from blood-pressure is afforded. It is my belief that the cavernous tissue covering the turbinated bones provides such a relief, and that this is one of the functions of the erectile tissues of the body. . . . Let this cavernous tissue be absent or greatly diminished, as is the case in atrophic rhinitis, and very little or no relief is afforded for the excessive blood-pressure in the capillary circulation in the skin of the face, and the result will be acne if any of the predisposing causes be present."

At the recent meeting of the French Association for the Advancement of the Sciences (*L'Union Médicale*, October 8, 1887), Dr. Arnozan presented a paper in which he referred to the frequent coincidence of cutaneous lesions of the nose and affections of the nasal fossæ. He reported several cases in which the cutaneous affection increased and diminished in severity coincidently with the varying progress of the associated disease of the deeper tissues. The author suggested several theories to account for the evident dependence of the acne upon the nasal affection, but did not insist upon any of them as a sufficient explanation of the etiological relation existing. He contented himself simply with the submission of the following conclusions:

1. There may exist a relation of cause and effect between the deep and the superficial affections of the nose.

2. The exploration of the nasal fossæ and the treatment, if occasion exists, of inflammation or chronic ulceration there present, should be undertaken in cases of cutaneous lesions of the nose.

The discovery by these two observers of a possible, if not probable, cause of many cases of acne of the nose will, it is to be hoped, lead to the adoption of a more successful method of treatment of this obstinate affection in the future than it has been possible to pursue in the past.

THE CASE OF THE CROWN PRINCE.

THE telegraphic reports up to date have brought nothing especially new, but have shown that German physicians are in a lively state of mind over the methods and treatment of the Crown Prince by Sir Morell Mackenzie. We trust that good feeling will be restored. It can never be forgotten that their own Virchow sent out the learned bulletins concerning warty growths, and that the scientific world drank in his lucid and convincing descriptions of the nature, cause, and course of "pachydermia verrucosa."

HOSPITAL SUNDAY COLLECTION.

THE total annual expenses of the twenty-eight hospitals in this city are $740,722. The total income from invested funds is $142,142; from pay patients, $163,808.69; from the city, $56,355. This leaves a deficit of about $300,000, to be made up by private subscriptions and by the hospital collections. There are annually treated 13,920 patients, of whom only twenty-five per cent. pay. In the out-patient departments there were treated 119,124 patients. These figures do not include the city hospitals, Bellevue and Charity, or the large independent dispensaries. The addition of these easily doubles the number of medical paupers of the city, bringing the total up to over quarter of a million.

The Hospital Saturday and Sunday Association have had favorably reported a scheme by which dispensaries connected with hospitals shall be entitled to share in the distribution of the general collection-fund.

Such a measure is hardly a just one, and we trust will not be adopted. There is no reason why a dispensary should be specially helped simply because it is attached to a hospital. Most of the largest and best dispensaries in the city, those really deserving support, are not connected with hospitals, while some of the out-patient departments of hospitals are pretentious superfluities.

THE HARTFORD HOSPITAL has received a bequest of $10,000 from the late Mr. William Boardman, of that city.

News of the Week.

Proprietary Medicines.—There are thirty-six thousand five hundred proprietary medicines in the market, according to Mr. Emlen Painter, Ph.G., in the *American Druggist*. He says of them that they are totally unworthy the distinction of being prescribed by medical gentlemen; that they are directly at variance with scientific progress; that their promoters have contributed absolutely nothing of value; and that, had they never existed, both medicine and pharmacy would have this day reached a higher plane in the development of science.

A writer in the *Provincial Medical Journal* describes the character of a fashionable consultant of the old school. He says of him: "He was hospitable to a degree, and a most entertaining, open-handed host he was. I don't think he ever gave a dinner-party to which some of his medical brethren were not asked. Being in a cathedral city, which was also a garrison town, many of these parties were of 'swell' description, but the good old fellow, always standing up for his profession, deemed his medical brethren good enough company for anyone—titled or untitled, bishops, deans, or generals." It was certainly kind of the old fellow to think his medical brethren proper company for clergymen, etc., but the remarks imply a very low social level for the English doctor.

Peddling and Prescribing Glasses.—Dr. L. Webster Fox and Dr. G. M. Gould have recently made a plea for a law restraining pedlers, jewellers, and opticians from prescribing glasses. They cite many cases of injury, often permanent, to eyes from errors due to ignorance, and claim that such "opticians" should be as much under legal restraint as druggists.

A Temperance Medical Journal, under the title of the *Medical Investigator*, is to be published by Dr. S. F. Smith, of Louisville, Ky.

A New Ailment is stated to have shown itself among telegraph operators—namely, the dropping off, one after the other, of the finger-nails. Two cases have recently occurred in otherwise healthy subjects. The curious affection is thought to be due to the constant jar caused by hammering and pushing with the finger-ends in working the Morse system of telegraphy.—*Journal of the American Medical Association.*

Exercise in the Treatment of Heart Disease.—For generations the main idea in the treatment of organic heart disease has been physical rest to diminish the labor of the damaged organ. We have been in the habit of prohibiting all forms of active labor to the sufferers from cardiac disease, and the principle of our treatment has been the unexpressed but ever-present idea, accepted as a self-evident axiom, that perfect rest was the best means of securing muscular compensation. Professor Oertel's experiments and results have come with startling surprise upon those who forgot to distinguish between a useful principle and the exceptions which the multiformity of disease renders it imperative to recognize. As is well known, he treats a considerable proportion of cases of organic heart disease by regulated exercise, especially graduated ascents of mountains, and his results place the value of his method beyond reasonable dispute. There is nothing really surprising either in his treatment or the success which has attended it. A little reflection will suffice to convince us that, while rest is often useful, and indeed quite indispensable, in heart disease, there are yet many cases in which well-regulated exercise will improve the nutrition of the cardiac muscle, as of the rest of the muscular system, and hence tend to the promotion of circulatory vigor.

The International Medical and Surgical Synopsis is the title of a new journal published monthly in St. Louis.

The Mortality from Total Extirpation of the Uterus has been of late immensely reduced. In two hundred and seventy-seven operations performed last year by Schröder, Hofmeier, Martin, Olshausen, Fritsch, and Leopold, the per centage of deaths was only 14.5. Fritsch and Leopold have reduced their mortality rate in this operation to 10.1 and 6.2 per cent., respectively.

Another Medical College in Philadelphia.—Application was made to the Court of Common Pleas of Philadelphia, November 1, 1887, for a charter for the Burton Medical College Association, whose purpose is "to establish a college to be known as the Burton Medical College, and subsequently, in connection therewith, a hospital for clinical advantages."

Two New Salicylates have been recently introduced into therapeutics—salicylate of mercury and salicylate of lithia.

Strophanthus and Ether.—Dr. F. Broadbent finds that the addition of ether to the dose of strophanthus is of great use in cardiac affections.

German Opinion of American Medicine.—Dr. Frank Donaldson, Jr., writing from Berlin to the *Maryland Medical Journal*, says: "A very short acquaintance with Berlin physicians and scientists suffices to give the quietus to the American's conceit of American medicine. I do not believe it too broad a statement to say that many Germans do not consider medicine, as such, to exist in America. They certainly have a supreme contempt for our medical schools and our medical teaching. In general, one is at a loss, at first, to account for this state of affairs, for most of the German physicians read English and know well the work and works of prominent men in the different large cities. The immediate cause, however, of this very poor opinion of American medicine is the average medical student who comes to Germany, supposed to study. Of course there are exceptions. As a rule, however, they are uneducated and unscientific men or boys, as the case may be. I have myself come across a number of such cases—one gentleman, for instance, who hails from the Far West, and who proposes to *finish* his studies in Berlin, and will take this Semeister: Physical Diagnosis, Experimental Physiology, Diseases of Women, Surgery, and Obstetrics. I overheard this gentleman holding forth on the progress of medicine in the West, and he gave this instance of the remarkable strides medicine was making in his native town: *A friend of his in Springfield, O., or Ill.*, has performed eight hundred (!) ovariotomies. A German

who heard the story very quietly asked if there were any women left in that place! Still another was heard to remark that in America we did not have the time to '*monkey*' with science. When we reflect that this city is full of just such men, is it to be wondered that one should be asked, 'Do you know cocaine in America?' (and this from an intelligent man) and from another, great surprise that we use antipyrine and have seen the tubercle bacillus."

In a recent Work on Diabetes Professor Ebstein claims that it is an independent disease, due to a diminished activity of the protoplasm, in consequence of which too small a production of carbonic acid gas takes place in the tissues. The glycogen not being fully broken up, is carried to the kidneys and eliminated. Ebstein appears to regard diabetes as a vice of the tissue protoplasm, rather than a disorder of nerve-centres. He recommends a diet of meat, fats, some bread, and Carlsbad and carbonated waters.

The Educational Systems of all countries are just now undergoing a pretty thorough shaking up. The criticisms made sometime ago on the London schools by Dr. Crichton Brown, though not free from bias and sensationalism, awakened a useful discussion. This has been transferred to Paris, and at the last Congress of German Naturalists and Physicians, Professor Preyer made a most violent onslaught on the gymnasia and "Realschulen" of Germany. His address called forth great applause and some hisses.

The Zurich Congress on Alcohol.—The *Journal of Inebriety* says: "A large gathering of statesmen, philanthropists, and physicians discussed the subject of alcohol in all its phases at Zurich, Switzerland, last August. On the question of the food value of alcohol, a unanimous conclusion was reached denying all nutrient value. On the medicinal value of alcohol in the sick-room, no agreement was reached." A Congress whose labors resulted in agreeing on a physiological untruth, and disagreeing on an evident clinical fact, needs, apparently, the infusion of a little intelligence into its members and managers.

A New Medical Society has been formed by the physicians of St. Paul and Minneapolis, to be known as the "Minnesota Academy of Medicine." There will be some twenty members from each city, and the meetings will alternate between the two places.

The New Medical Practice Act in Illinois.—The new law has required much labor, but the result has been satisfactory. Eleven suits have been pushed to successful conclusions. The most signal benefit has been in ridding the State of the itinerant nostrum-vendors, with their brass-band and other accompaniments. July 1st, twenty of these shows were in the State, which tendered $1,500 per month in fees for licenses, all of which were refused.

A Medical College in Bad Standing.—The Toledo Medical College not having taken advantage of the opportunities given it to correct the abuses complained of previously, it was declared to be not in good standing under the present Medical Practice Act.

Lady Dentists.—The Committee of the National Dental Hospital, Great Portland Street, London, W., have resolved to admit ladies to be trained as dentists at this hospital.

The Proper Course.—"In case of an accident, doctor—a broken leg, for instance—what is best to be done while waiting for the physician?" "Well," said the doctor, "I think the best thing to be done is to get the money ready for him."—*Puck.*

There are Fifteen Thousand Nurses in Great Britain, and Mr. Henry C. Burnett advocates the establishment of a national pension fund for their benefit and that of hospital officials.

The Late Dr. William M. Chamberlain.—At the regular meeting of the Medical Board of Charity Hospital, held November 1, 1887, the following preamble and resolutions were unanimously adopted:

Whereas, William M. Chamberlain, M.D., one of the oldest and most honored members of this board, has recently been removed by death;

Resolved, That we hereby express our deep sense of the loss which the Medical Board of Charity Hospital has sustained in his decease.

Resolved, That we bear testimony to his high professional and literary attainments, to the sterling integrity of his character, to his kindly social qualities, to his sound judgment and skill, and to his devotion to the interests of Charity Hospital, in which he served for more than sixteen years as visiting physician, and subsequently as consulting physician to the time of his death.

Resolved, That a copy of these resolutions be transmitted to the medical journals of this city, and to the family of our deceased associate, to whom we desire to extend our sincere sympathy in their affliction.

F. N. Otis, M.D.,
J. Lewis Smith, M.D.,
Robert W. Taylor, M.D.

Woman's Hospital.—Dr. John H. Swasey has been appointed Assistant Surgeon to the Woman's Hospital, *vice* Dr. B. F. Dawson resigned.

Vaccination from the Buffalo.—The experiment has been tried in India, during last year, of vaccinating from a young buffalo, instead of from a calf, and the results are said by an Indian contemporary to have been "in every way satisfactory."

Belgian Judges on the Value of Medical Services.—Belgian judges would seem to entertain a very poor appreciation of the value of a medical man's time and services, if we may judge by a case that has recently been tried at Louvain. A medical man, in country practice, having attended a wealthy old bachelor for some five months before he died, sent in his account to the executors, who disputed it as exorbitant, and so the doctor was compelled to endeavor to recover his fees by an action in a court of law. The account amounted to 1,175 francs ($235), which comprised thirty-eight consultations with a Brussels physician at 20 fr. ($4); fifty-six day-visits at 5 fr. ($1), and five night-visits at 10 fr. (330 fr.); medicines, 85 fr. The defendants denied that the visits with the physician were consultations, and

they offered 2 fr. for each day-visit and 3 fr. for each night-visit. The court, however, "considering that the patient lived three miles from the doctor, who was obliged to make visits at definite predetermined hours along with a colleague from Brussels, and that night-journeys, especially in winter, are troublesome," decided that "day-visits might be equitably fixed at 2.50 fr. and night-visits at 5 fr.;" so that all that was allowed the unfortunate practitioner was 235 fr. for ninety-four day-visits, 25 fr. for five night-visits, and 85 fr. for medicines (the only item which was not disputed), so that the total was cut down to 345 fr. ($69)—a magnificent remuneration, indeed, for such an attendance! A cab-driver would certainly expect more for a similar number of journeys.—*Lancet.*

Conference of Missionary Medical Students.—A missionary conference of medical students of New York was held in this city last week. These conferences are held annually, the present being the fourth. The Rev. Dr. George E. Post, M.D., of Beyroot, Syria, delivered an address on "Medical Missions as a Means of Access to Mahometans." R. P. Wilder, of the New York Theological Seminary, followed with a religious discourse, his subject being "The Master's Last Command." An hour's quiz, conducted by C. K. Ober, College Secretary of the International Committee, closed the proceedings of the afternoon session. In the evening, the conference reassembled in Dockstader's Theatre, with C. K. Ober in the chair. Yan Phon Lee, a Chinese graduate of Yale University, spoke at some length upon the trials and hardships of medical missionary work in China, and the comparative results. Dr. H. N. Allen, Special Envoy to the King of Corea, and the Rev. James Johnson, of Glasgow, Scotland, also made addresses.

Tight Lacing and Bright's Disease.—Dr. Neftel claims that tight lacing predisposes to renal disease and phthisis, but renal disease is more common in males than in females.

The Doctor and the Detectives.—The *Medical and Surgical Reporter* states that "a circular has recently been issued by Pinkerton's National Detective Agency asking each physician who receives a copy to give information to the agency in case a suspicious person should come to him for treatment of a gunshot wound of the jaw. It seems that on the morning of Friday, September 30, 1887, burglars entered the residence of the cashier of the Farmers' Bank of New Castle, Del., where the bank is also located, and attempted to overpower the cashier and his family. A fight ensued, and the cashier shot and wounded one of the burglars. The ball is supposed to have entered the mouth of the burglar, shattering the jawbone and carrying away with it a portion of the bone—a piece of which has been found in the blood which came from the wound, and experts pronounce it a part of the jaw-bone. The detective agency wishes the co-operation of medical men in securing the apprehension of this criminal, and we hope may have it." Our contemporary thinks that the doctor ought to assist the detectives and inform on the burglar. But the doctor is not in the detective business. The two callings are quite antagonistic. The doctor deals in the patient's secrets to help the patient, not to betray him. And again, a poor man with a jaw shot off is pretty well punished already.

Reviews and Notices of Books.

De l'Electricité comme Agent thérapeutique en Gynécologie. Par le Docteur Paul F. Mundé. Traduit, avec l'autorisation de l'auteur, et annoté par le Docteur P. Ménière. Paris: Octave Doin. 1888.

We are pleased to call attention to the compliment paid to Dr. Mundé's well-known work, by a translation into French. Dr. Ménière has added a number of notes, to adapt it more to the needs of French physicians.

Die Allgemeine Pathologie oder die Lehre von den Ursachen und dem Wesen der Krankheitsprocesse. Von Dr. Edwin Klebs, Erster Theil. Die Krankheitsursachen Allgemeine Pathologische Aetiologie. Mit Theilweise farbigen Abbildungen im text und 8 farbentafeln. Jena. Verlag von Gustav Fischer. 1887.

This book belongs to the highest class of medical works and deserves a much more comprehensive and critical notice than we have space to give to it. The first volume, which is all that has so far appeared, deals chiefly with the subject of pathogenic micro-organisms, their life-history, modes of culture and relation to disease. It is essentially a work on bacteriology, but it is a most complete one, copiously illustrated and containing references to all the work that has been done in this line by the author, and by such other pathologists as have really contributed to the science. Prof. Klebs has been himself a leader in this kind of work, and has indeed made some rather premature announcements of discoveries of specific bacteria. No one can doubt, however, his learning, or ability to present the subject with thoroughness.

The author's study of heredity in its relation to predisposition to, or transmission of disease is very suggestive.

The illustrations in the book are numerous, and are as a rule beautifully executed. The work is a timely one, and most creditable to the distinguished, if sometimes erratic, pathologist who is its author.

Guide Pratique pour l'Analyse chimique et microscopique de L'Urine, des Sediments et des Calculs Urinares. Par le Dr. L. Gautier. Avec 90 gravures dans le texte. Paris: Librairie F. Savy, 1887, 800 pp. 248.

This book is very complete, especially in its description of chemical tests, and in its illustration and description of all the different constituents of the urine. We have seen no text-book that condensed so much in so small a space. The illustrations are numerous and accurate. Not much space is given to pathology.

A Reference Handbook of the Medical Sciences, embracing the entire Range of Scientific and Practical Medicine and allied Science. By various writers. Illustrated by Chromolithographs and fine wood-engravings. Edited by Albert H. Buck, M. D., New York City. Volume V. New York: William Wood & Company. 1887.

This great work is now in the hands of so many of the physicians of this country, and is so well known and appreciated, that little remains to be said of it. It speaks for itself, and it is sufficient for the reviewer to point out briefly the character of the contents of this particular volume which, make it perhaps one of the best, if such a comparison is possible, of the series. The volume begins with Miliaria and ends with Pott's Disease.

Among the more important articles are, Mortality, Mountain Climates, Anomalies of Muscles, Histology of Muscular Tissue, Myopia, Surgical Anatomy of the Neck, Necrosis, Neuralgia, Neuromimesis, Personal Nomenclature. Diseases of the Nose and Nasal Pharynx, Training School for Nurses, Nutrition, Hygiene of Occupation. Ophthalmoscope and Opthalmoscopy, Opium, Optic Nerve, Optometry, History of Orthopædic Surgery, Osteotomy, Diseases of the Ovaries, Ovariotomy, Injuries and Diseases of the Pancreas, Paralysis Agitans, Diphtheritic Paralysis, Infantile Spinal Paralysis, Paraplegia, Injuries and Diseases of the Patella, Pelvic Cellulitis, Pelviperitonitis, Disease and Injuries of the Penis, Pericarditis, Lacerated Perineum, Surgical Anatomy of the male Perineum, Periodicity in Disease, Peritoneum, Peritonitis, Pessaries, Pharmacopœia, Photo-Micrography in Medicine, Phthisis Pulmonalis, Physical Measurements, Medical Physiognomy, Placenta, Plastic Surgery, Pleurisy, Pneumonia in Children, Poisonous insects, Poisons, Diagnosis of Local Lesions in the Pons Varolii and Medulla Oblongata, Post-Mortem Examinations, Potassium, Pott's Disease. There are, in addition, very many shorter articles on subjects in dermatology, materia medica, health resorts, etc. Indeed, it would be difficult to find any subject relating to the science of medicine in its broadest sense which is not here treated of with more or less detail as the importance of the subject may demand The volume is illustrated by upwards of 750 wood-cuts and seven lithographic plates, printed in black and colors. The contributors, from all parts of the United States and Canada, number eighty-six.

Mechanical Massage. By Geo. H. Taylor, M.D. New York: John B. Alden. 1887.

This is a book, intended for popular use, explaining a system of massage by means of various forms of machinery.

A Practical Treatise on Obstetrics. By Dr. A. Charpentier, Adjunct Professor at the Faculty of Medicine, Paris. Translated under the Supervision of, and with Notes and Additions by Egbert H. Grandin, M.D., Obstetric Surgeon to the New York Maternity Hospital, Instructor in Gynecology at the New York Polyclinic, Fellow of the Obstetrical Society, etc. In four volumes, with numerous wood engravings and colored plates. New York: William Wood & Co. 1887.

This treatise on obstetrics forms the first four volumes of the "Cyclopædia of Obstetrics and Gynecology," issued monthly during 1887 by William Wood & Co. The first volume treats of the anatomy of the internal and external genitals, menstruation and fecundation, and normal pregnancy and labor. In the second volume the pathology of pregnancy is considered. Here the author treats of the diseases to which the pregnant woman is liable, of diseases of the ovum and of the fœtus, of miscarriage, of extra-uterine pregnancy, and of the effect upon the course of pregnancy of any intercurrent disease to which the woman may become subject. Volume third includes a consideration of the pathology of labor. The author reviews all the factors which may be concerned in the production of dystocia, and considers the means best adapted for the relief of this condition. A special chapter is devoted to ergot, its physiological and pathological action, and the indications for its use during labor and during the puerperium. In the fourth volume the pathology of the puerperium and the various obstetric operations are considered in detail. The work is profusely, though judiciously, illustrated, the four volumes containing about 750 wood engravings and 7 colored plates. Charpentier's work is recognized to be the most complete and trustworthy treatise on obstetrics in existence in any language, and an incalculable service has been rendered English-speaking physicians in giving them this translation. But despite the writer's acknowledged authority as an obstetrician, there are yet some points upon which his views are at variance with those of the majority of teachers. These points have not escaped the critical eye of the editor, who has added copious notes, whenever it seemed necessary to warn the reader against what might be considered erroneous teaching. The work as it now appears may therefore be regarded justly as the standard authority, as the latest and the best treatise on obstetrics in the English, or indeed in any other, language. If the use of so hackneyed an expression may be allowed for the sake of the truth which it contains, we would say with emphasis that no practising physician can afford to be without this cyclopedia.

Diseases of the Female Mammary Glands. By Th. Billroth, M.D., Professor of Surgery at the Royal University, Vienna. Edited by Egbert H. Grandin M.D., Obstetric Surgeon to the New York Maternity Hospital; Instructor in Gynecology at the New York Polyclinic; Fellow of the Obstetrical Society, etc.

New Growths of the Uterus. By A. Gusserow, M.D., Professor of Obstetrics and Gynecology at the University of Berlin. Translated and Edited by Edmund C. Wendt, M.D., of New York. New York: William Wood and Company. 1887.

These two works together make up Volume IX. of the Cyclopædia of Obstetrics and Gynecology, published in Wood's series for 1887. The first named work treats of the anomalies and diseases, puerperal and non-puerperal, including tumors of the mammary gland in woman. There is also a chapter on the operation for removal of the mamma and axillary glands. The second part, embracing about two-thirds of the volume, is on New Growths of the Uterus. It is a somewhat free translation of the second edition of Gusserow's work, containing also some reports of cases and tables which appeared in the first edition, but were, not wisely, it would seem, omitted from the second. Each of these two books is a masterpiece of its kind, and the two together combine to make this one of the most useful volumes of the set.

Quarantine and Anti-quarantine.—As was anticipated, the International Congress of Hygiene at Vienna offered an opportunity for a duel of words between the leaders of sanitation, who differ so widely concerning the best means of keeping cholera out of a given territory. The members of the Congress included many members of the last international quarantine commission, which met at Rome, and at which there were distinctly formed a quarantine party and an anti-quarantine party. Professor Gruber, of Vienna, described his experience with cholera in Austro-Hungary in 1885 and 1886, and said that the intercourse between human beings provided the greatest opportunity for the spread of cholera, but its spread depended largely upon the season and weather. Professor Gruber expressed himself as a firm believer in Koch's bacillus theory, and a strong adherent of the quarantine system. Two Japanese delegates then stated that cholera was always introduced into Japan by English or French ships coming from China. When Max von Pettenkofer, of Munich, of the anti-quarantine school, and Dr. Proust, of Paris, his able opponent, joined in the debate, the climax of the discussion was reached. Pettenkofer upheld the English idea of sanitary preparation to prevent the disease from getting a foothold, and claimed that, while he did not deny the discovery of the bacillus by Koch, that its existence alone could not explain all the phases of the disease as seen in India and elsewhere. Dr. Proust advocated isolation, detention, and disinfection, and the Congress adopted by a large majority five resolutions, moved by him, setting forth the views of the quarantine party.—*Sanitary News*, October 8, 1887.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, November 17, 1887.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

A LARGE audience assembled to listen to the anniversary discourse. There were seated upon the platform Dr. John S. Billings, of Washington; Dr. Fordyce Barker, ex-President; Drs. Charles Carroll Lee and William H. Draper, Vice-Presidents; and Dr. Andrew H. Smith.

On motion of DR. JACOBUS, the Secretary, and in compliance with the recommendation of the Council, the regular order of business was omitted.

THE PRESIDENT then gave a brief history of the life of the Academy during the current year, which showed that there had been successful scientific work and increasing prosperity. With this there had been sad losses; eight Fellows having been removed by death, whose names and memories would not be forgotten.

During the year 62 new members had been elected, making a total of 511 resident Fellows; the largest number since the incorporation of the Academy.

To the library there had been added 1,120 bound volumes, and 400 pamphlets. By a special donation the *Library Fund* had been increased by $5,000, making $10,000 total, the proceeds of which could be used for the purchase of new books, etc. There would soon be transferred to the library a donation of a special library on malformations of 4,000 volumes.

The President then gave a brief *résumé* of the scientific work of the year, and alluded to the immense value to the public of the recognition of the presence of

CHOLERA AT THE PORT OF NEW YORK

by the bacteriological investigations of medical experts.

The Health Department and the New York Academy of Medicine had joined hands.

He expressed the hope that the public would appreciate the good the Academy was trying to do, and some day give tangible evidence of that appreciation by such liberal donations as would enable it to build a suitable building for the accommodation of its rapidly increasing library and for the proper performance of scientific work.

The circular which had been addressed to the profession and the public, and signed by a committee of thirty, was then read.

TWO HUNDRED THOUSAND DOLLARS

would be asked for, with the confident expectation that that amount would be obtained, which would enable the Academy to build a fire-proof building.

After pointing out some of the relations existing between the public and the medical profession, the President introduced the orator of the evening, DR. ANDREW H. SMITH, who delivered the anniversary discourse, on

THE FAMILY PHYSICIAN OF THE FUTURE,

in which he spoke, first, of the diversity of occupations of the human race. But not until comparatively modern times did "the healing art" take an independent position, and he then considered what that position was at the present time. Did medicine hold the place in public estimation which it should? Certainly it did not. Notwithstanding the great advancement which had been made, it was still unable to make itself heard above the clamor of ignorance, superstition, and charlatanry.

Even hospitals, though dependent upon the profession, did not invite medical men to take a share in their management.

In this city the profession had no voice whatever in the selection of the Board of Health, and the law specifically provided that it should not be presided over by a medical man. With few exceptions, the medical man was known only in the vicinity in which he lived. The profession as a whole exercised no important influence in the community, although the science of medicine was but a fragment of a far greater subject which had engaged the attention of the most learned and renowned men of the world. Both as a science and an art it had occupied itself too much with individuals, and not sufficiently with other organizations. It had studied only to relieve the present suffering of the individual, and prolong his life, and the physical well-being of the race had been left almost entirely without consideration.

The relation of the family physician to families was then pictured, and it seemed that in the cities, at least, there was scarcely a place for him to stand. For Drs. A, B, C, D, and E attended to the various special diseases, and Dr. F was merely asked to tell who the best man was in each of these departments. Medicine, however, could be a power in the world only as it was

REPRESENTED BY THE GENERAL PRACTITIONER,

and in proportion as specialism became excluded from the family physician medicine became restricted in its scope. The aid of the specialist would always be required, but the time would come when such aid would be rendered only at the instance of the family practitioner.

Attention was then directed to the tendency of modern medicine, which was toward the prevention of disease. The triumphs of antiseptic surgery were much more notable in keeping germs out of the system than in getting rid of them after they had effected an entrance. Ultimately

THE CHIEF PROVINCE OF THE FAMILY PHYSICIAN

would be to prevent suffering. The relief of suffering was godlike, but to prevent suffering was a still higher office.

The intimate relation which should exist between family and physician was then sketched, and it included advice concerning all hygienic and sanitary questions, hours of recreation, work, and entertainment, eating and drinking, activity in business, etc. Who were our natural protectors, if not family physicians?

In order to show in detail what the relation should be between the medical practitioner and the families under his charge, he took up

THE LIFE OF A YOUNG MARRIED PAIR.

In the first place, the medical man should be selected with the greatest care, and should be of an age that, in the ordinary course of human events, would allow of a long-continued service.

The medical history of the man and of the woman, as far as possible, should be recorded, containing a careful physical examination. Chronic disease should not go undetected, and sudden death could not occur without forewarning should that be done thoroughly.

The birth of the children, the progress of dentition, the age at which each child walked and talked, the occurrence of the contagious diseases of childhood, etc., should all be recorded, and it was only by such carefully kept records that the physician could become properly acquainted with the constitution of the patient.

"The proper kind of treatment for some diseases begins one hundred years before the birth of the child," had been said by Dr. Holmes.

Dr. Smith then spoke of the great advantages afforded by such records. Among the very earliest and important requirements in the rearing of children should be

OBEDIENCE AT HOME.

The influence of this could be seen when the child began to go to school, or when it came under treatment for any disease, and under the influence of the general laws which regulated the development of each mental faculty. Children with damaged heart-valves should not

be allowed to engage in the sports of athletic clubs, and the influence of efforts at abstruse reasoning upon delicate, highly susceptible, or impaired nervous systems should be under the steady surveillance of the family physician. So, in a thousand ways, the physician should have his place on the consulting board of his families. The occupations of the boys should be largely influenced by the decision of the family physician, who should always be as welcome and feel as free at the domestic board as in his own home. His advice should be sought with regard to night-entertainments, dress, the selection of a new residence, etc. A house occupied by a consumptive, even years before, should not be occupied by the healthy until it had been thoroughly cleansed and disinfected.

This partial sketch of what he believed would be considered the duty of the family physician was closed by a consideration of the question of time required to carry out the suggested method, and how present arrangements, which offered an impassable barrier, could be so modified as to permit of its application.

Such a physician must necessarily be a man of varied culture and great learning, and he would have use for a more extended knowledge than any man in the community.

Under all circumstances and in all positions, such a man would so represent the higher and broader aims of medicine as to give the profession a standing before the world commensurate with the dignity and importance of his office.

This was more than an ideal sketch; it was a prophecy which he believed would be fulfilled. The Academy should be like the true family physician, and represent medicine in its largest sense and fullest development.

At the close of the address, which was well received, the audience was invited to inspect the library and the reading-rooms, and the Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 12, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. A. P. Dudley presented the

TUBES AND OVARIES

removed from a woman fifty-one years of age. They did not show any pathological change. The history of the case contained the principal point of interest. She was married when thirty-three years of age, was the mother of four children, and had never had a miscarriage. Her first delivery was normal and not rapid. In her last labor, eleven years ago, she was delivered rapidly of a child that weighed ten and a half pounds, and had never been well since. During these eleven years she had been in bed most of the time; at no time had she been able to walk the distance of the length of a block. During the last three years she had not been out of bed, except to use the commode. Her menstrual life was about normal, and she never had a leucorrhœal discharge. There was chronic constipation, but no vesical symptoms.

Her chief complaint was concerning

PAIN IN THE SPLENIC REGION,

which was not constant, but was severe whenever she was upon her feet. There was fixed retroversion of the uterus. A great variety of diagnoses had been made, and among these aneurism. Dr. Dudley was unable to obtain any positive evidence of aneurism, although there was marked pulsation directly over the abdominal aorta, with a moderate amount of thickening, apparently, just below the umbilicus. He recommended exploratory incision, and performed the operation, October 11th. He introduced the whole hand into the peritoneal cavity, found the spleen small and without adhesions. Nothing pathological was found at the site of the pain of which she had complained. The aorta was normal, except that it apparently bifurcated high up, and at that point it was quite large.

THE MENOPAUSE WAS COMPLETE ONE YEAR AGO.

In the pelvis the lower part of the descending colon was adherent to the broad ligament and ovary. The uterus was retroverted and firmly adherent. The uterus was not reduced in size.

Adhesions were broken up and the uterus liberated. Both broad ligaments were filled with knotted veins. Both tubes and ovaries were removed. Sufficient of the broad ligaments was caught up to include the varices and the round ligaments, and when this had been done the uterus assumed the normal position, and was thus also separated from the fresh surface of the adhesions that had been broken up behind it. The patient was doing well, had not needed any opium, and had been free from pain. The question arose, *How much good can be done by removal of the tubes and ovaries after the menopause?*

ECHINOCOCCUS-CYSTS OF THE LIVER AND PERITONEUM.

Dr. Ira J. VanGieson, presented specimens which were taken from the body of a middle-aged German woman, who was delirious a few days before death, but gave no symptoms referable to the parasitic lesion. The cysts occurred in the following situations:

(1) Partially embedded in the right lobe of the liver, a little external of the gall-bladder, there was a soft globular sac about two and a half inches in diameter. The wall of the sac contained a few blood-vessels, and the exposed surface of the sac was slightly adherent to the surrounding tissues. (2) Attached to the omentum in the right lumbar region was an oval sac $3\frac{1}{2}$ by $1\frac{1}{2}$ inches in diameter. (3) In the hypogastric area, adherent to the omentum, was a kidney-shaped sac, 4 by $1\frac{1}{2}$ inches in diameter. (4) In the left inguinal region were two sacs; one, oval in shape ($2\frac{1}{2}$ by 1 inches in diameter), lying against the abdominal wall; the other, somewhat smaller, lying loosely over the sigmoid flexure. (5) The right inguinal region contained a group of four smaller sacs, lying distinct from each other on the fascia of the psoas-muscle. One of this group was adherent to the vermiform appendix near its junction with the cæcum. (6) Embedded in the mesentery, about the size and shape of the mesenteric glands, were several other sacs. (7) On the anterior surface of the uterus were a number of small cysts about the size of peas; on the anterior lip of the cervix uteri was a larger one, about $1\frac{1}{2}$ inch in diameter.

These sacs, when opened, were found packed with larger and smaller translucent, mottled gray and white cysts, associated with a varying amount of soft, white material. The cysts were collapsed and tightly rolled, so as to become spindle-shaped. Frequently, several cysts were rolled together in a single coil. Scrapings from the cyst-walls, examined microscopically, showed fat globules, granular matter, cholesterin crystals, and fragments of the peculiarly laminated outer wall of the cysts. Hooklets and scolices were not found, so the cysts might be termed sterile.

The President regarded the case as interesting, because of the rarity of the peritoneal echinococcus-cysts in such numbers. He could recall only two cases where the peritoneal cysts were so numerous and large.

Dr. VanGieson also presented a specimen of

PENDULOUS UTERINE MYOMA,

which he found suspended from the cervix uteri and completely occluding the vagina. It was taken from the body of an old woman who died of acute exudative peri-

tonitis in Charity Hospital. The tumor closely resembled a human heart, measured 4½ by 5 inches in diameter, and weighed a little over one pound. Its long axis corresponded to the long axis of the vagina. Its base was against the cervix, to the posterior lip of which it was attached by a slender flattened pedicle half an inch broad and one-eighth of an inch thick. The discolored apex protruded from the vulva about one and a half inch. The tumor was moderately adherent to the posterior wall of the vagina.

Dr. John C. Peters, Chairman of the Committee appointed to prepare a

MEMORIAL NOTE ON THE DEATH OF ALONZO CLARK, M.D., LL.D.,

read the following, which was accepted and ordered to be published in the minutes:

It is eminently proper that the New York Pathological Society should honor the memory of Dr. Alonzo Clark, for he was always its friend, and often its teacher and counsellor, for nearly fifty years.

But we are not called to mourn his loss as those who cannot and will not be comforted, for he lived an unusually long, healthy, honored, and useful life, which was only ended by great age and its attendant infirmities, and these, moreover, were so wearing that he longed to be released from them. Even under these distressing circumstances, we cannot go as far as Diedrich Knickerbocker, who says the death of a great man is no very inconsolable matter of sorrow, and that no fact is more manifest than that the death, even of a very wise man, is a thing of very little importance: nor agree with Pliny, who says: "Of what consequence is it that individuals come and go? Sage follows on the footsteps of sage; one hero steps out of his triumphal car to make way for another, and of the proudest monarch it is merely said, 'He slept with his fathers and his successor reigned in his stead.' The world cares but little for their loss, and if left to itself would soon forget to grieve. It is the biographer and the historian who generally have the whole burthen of grief to sustain. They inflate the people with sighs they never heaved, and deluge them with tears they never dreamed of shedding." All this is not true of Dr. Clark, who has, and long will have, many sincere mourners.

It is more than ten years ago since many of us noticed, with sincere regret, that age and increasing weakness no longer permitted him to attend our meetings with his usual regularity, and that meant a great deal for Dr. Clark, as it is said that before this, in his long career, he had never missed a college, hospital, or consultation appointment. Many months ago we were pained to find that progressing debility rendered intercourse with him uncertain and difficult; still he was always pleased to see his old friends, and it was frequently evident that he had not lost his interest in this Society.

Finally he could only sit, with mingled Christian and Socratic resignation, calmly noting the slow but relentless approaches of that Great Destroyer which he had so often baffled in the service of others, and so frequently triumphed over.

But before we were called upon to pay him our last tributes of love and respect, we were suddenly summoned to mourn the loss of his great and pleasant rival, Dr. Austin Flint.

Dr. Clark was over eighty-one, and had been a leader in this Society for forty-three years. Dr. Flint was only seventy-four years of age, and had worked with us usefully and agreeably for twenty-seven years. But Dr. Flint was still healthy, active, and elastic in body and mind, and altogether excellent. Some of us expected to meet him for a decade or more. Like Dr. Clark he was loaded down with professional honors, and had a very large clientage of friends and doctors. He, too, was a great medical teacher and a famed hospital and consulting physician. Dr. Clark had often wished to reach his eightieth year, and hoped to do this with his eyes undimmed and his strength not greatly abated. Dr. Flint had frequently signified his preference for sudden death. The wishes of both were granted. After an unusually busy, honorable, and successful day, Dr. Flint was stricken down so quickly that he died and made no sign; and so mercifully that we had the firm assurance that he felt no suffering. Dr. Clark was still looking quietly toward that eternity for which he had no fears, and submitting to his lingering fate with dignity and complete composure. If Dr. Flint had lived another short year he would have been publicly crowned in Europe and America with the highest medical honors which had ever been given to any American physician; and Dr. Clark had long been worthy of them. But, as it were, in the twinkling of an eye one great New York consulting physician was dead and another was completely incapacitated.

"Both had minds of singular breadth and wisdom, accustomed to rest their judgments upon an enormous range of experience and learning; to hearts as large and warm as their intellects were comprehensive they added a gracious gentleness and dignity of nature which adorned and rounded out characters of exceeding completeness and loveliness" (C. A. Dana).

Both had often witnessed every shade of human suffering and agony; both had watched death in all the numberless and dreadful varieties in which it appears to great medical counsellors and hospital physicians, in widespread epidemics, malignant fevers, and swift inflammations, and in all the slower but equally relentless steps of malevolent chronic disease. The one was spared all warning of his end, the other was destined to drain the last bitter dregs of the cup of misery. But so completely master of himself was Dr. Clark, that we saw no signs of unmanly fear, or even of impatience; and so completely had he always kept fully abreast of his profession that he was not called upon to sorrow for any great professional mistakes or deficiencies, much less of crimes. His medical conscience was clear, and his end was that of the good and faithful servant who had increased his talents seventy and even an hundred fold.

We should remember both Drs. Clark and Flint because much of their best and most original work was done with and for this Society, and that in such abundance that the mere record of it fills several hundred pages of our archives.

It is believed that Dr. Clark favored this Society more than any other. He joined it in the first year of its existence, viz., in 1844, and much of his newest and most interesting researches were first made public at our meetings. He from the very first reached a very prominent position in our ranks, for he was then over forty years of age, and in the very prime of his health and fame. He was already an excellent medical scholar; a singularly good clinical and didactic teacher; a noted hospital physician; a favorite counsellor of scores of general practitioners; and had long been doing earnest and honest work in the rapidly spreading fields of pathological science.

It is believed that Dr. Clark then and always regarded this Society as the most useful medical organization in this city. He certainly strove very hard to make it so. Your Committee has gone over much of our earlier records, and have been surprised at the very large number of rare and important specimens which he exhibited years ago, for himself and others; for many physicians preferred the clear and scientific way in which he could bring out their peculiarities to their own more imperfect efforts. He was then, as always, a most industrious and painstaking man, and it is scarcely an exaggeration to say that sooner or later he exhibited specimens of almost every fatal disease to which the human frame is liable.

Dr. Clark was gifted by nature with a most commanding, dignified, and comely presence. He was so large that it often seemed as if he must be unwieldy; but he was so careful and methodical in all his ways that he ever appeared untiring. He was not alone in some of

these characteristics, for there were giants in those days in the New York Pathological Society, and the magnificent forms of Willard Parker, Valentine Mott, William H. Van Buren, C. R. Gilman, Middleton Goldsmith, George Wilkes, T. M. Markoe, G. A. Sabine, L. A. Sayre, J. T. Metcalfe, S. S. Purple, T. M. Halstead, and others were often seen among us. But Dr. Clark towered above them all, the largest and most symmetrical, often the most learned and earnest, yet frequently the most genial and winning; for his kindliness and humor were quite as marked as his more solid qualities. The size and shapeliness of his person were only rivalled by the breadth, depth, and pleasantness of his mental and moral characteristics.

These physical and mental giants were closely matched in intellect and knowledge by many smaller personages which so often inclose precious gifts, like John A. Forrey, John A. Swett, Edward Delafield, James R. Wood, William C. Roberts, C. E. Isaacs, Robert Watts, the two little Peterses, and many others; yet Dr. Clark thought and spoke with ease and confidence among the quicker, and perhaps brighter, sallies of his less ponderous colleagues. He sometimes appeared very deliberate, for one of his most marked characteristics was his extreme accuracy. His love of precision led him to as careful a study with the microscope as the instruments of that time would permit, and it is believed that he was not only the earliest medical worker with the microscope in this city, but the first American physician to own a really good apparatus. However this may be, he certainly made almost all the earliest microscopical examinations which were made in this Society, for the specimens of others were constantly referred to him for more minute study. He continued to do this work with few rivals until the microscope fell into the hands of specialists; but the lamp which lighted up his own magnifier never went out until he had completely retired from practice.

In those early days the doctor's watch took the place of the clinical thermometer, and not only measured time, but tried to measure fever. Dr. Clark's timepiece was more accurate than the microscopes and thermometers of those times. He had many appointments to keep each day at college, hospitals, and especially at numerous consultations. Although he never kept a private carriage or used a hired one, he was never behind time. He never was seen hurried, much less excited, nor did he ever appear fatigued. He was always true to time, and as cool. He seemed as incapable of forgetting the exact hour of an appointment as he was of deliberately violating a promise. His high sense of honor and honesty he carried into all the affairs of life, especially into the study and treatment of disease. He knew when to give, and especially when to withhold, his medicines. He had so often seen nature do much that he had learned when to trust solely to her; but in peritonitis he frequently gave, and that successfully, hundreds of grains of opium in a day, for days and almost weeks together.

He went about on foot, because he regarded a certain amount of exercise necessary for his bulky frame. Besides, he was opposed to all display and ostentation. He was obliged to keep a score or less of horses at his country-place at Darien, Conn., but he used no carriages or horses in this city. He unobtrusively went his daily rounds, as if he was one of the least important of doctors. His love of truth and dislike of display also led him to prefer his ears to any instruments in examinations of the chest, although he and Dr. Cammann discovered and perfected the stethoscope which has been the favorite one all over the world for thirty years or more.

Our archives also preserve many instances of the remarkably earnest, honest, and masterful manner in which Dr. Clark led or followed the numerous discussions which arose in this Society. It was always evident that he had no fixed opinions or beliefs except such as were deeply founded upon well-assured facts. He often stripped off the rosy glamour with which more enthusiastic and imaginative men tricked out mere notions or hypotheses; but it was always evident that he had applied the same wholesome pruning process as relentlessly to his own visionary ideas, if he ever had any. He was always very courteous and fair in debate; he mingled great gentleness with extreme firmness, and was rarely worsted in argument for the lack of assured facts or solid reasoning. He was heard at his best in old-time discussions with Drs. Parker, Van Buren, Markoe, Isaacs, Metcalfe, Roberts, Watts, Peaslee, Dalton, Post, Jacobi, Buck, Sands, Krackowizer, Sabine, Shrady, and others. It was only occasionally that we could see how sharp and heavy in retort he could be. His bearing in these discussions was perfect. He never showed the slightest sign of impatience or annoyance, and used only the simple and clear eloquence of great and accurate knowledge, occasionally lightened up by a little humor, in preference to downright contradiction. He always appeared like one who had earnestly striven, and successfully, to learn all that was positively true in medicine, and had equally carefully avoided all that was immature and uncertain. Occasionally, if some new-comer endeavored to show that he knew more than the whole Pathological Society, Dr. Clark would bonnet him relentlessly.

Fortunately the Pathological Society has always had such reliable leaders, commencing with our first President, Dr. John A. Swett. The number of those who strove for mere verbal or windy victories has always been small.

The New York Pathological Society, although founded by young men, all under the thirties, is the oldest association of the kind in the world, preceding the London Pathological Society by two years. But Dr. Clark quickly joined it, as did Parker, Van Buren, and others of like stamp. Dr. Clark was long one of our great leaders. At the time of our founding he was the foremost pathologist in this country, and by his hard work and enthusiasm gave much impetus to the new Society and to the study of pathology all over the land. As far as mere pathology is concerned, the places of Drs. Clark and Flint have long been filled, but as wise, considerate, experienced, and kind physicians, advisers, and friends, their loss will long be felt by those who knew them best.

Dr. Flint will live in his writings. The public fame of Dr. Clark is especially intrusted to the College of Physicians and Surgeons, to this and other societies, and to the hospitals he served so long and so well. They will not let the words of Diedrich Knickerbocker become true and his name forgotten.

J. C. Peters,
W. M. Carpenter,
W. P. Northrup,
Committee.

Enema Lesions.—Dr. Nordmann, of Basle, has published a description of lesions due to the operation of administering enemata (*The Lancet*, October 8, 1887). They include three complete perforations and ulcers, and wounds of various depths and sizes. The causes of these lesions seem to have been the use of defective instruments, ignorance of the direction of the rectum, catching of the transverse fold on the tube, extreme irritation of the mucous membrane of the bowel, and obstructions caused by certain conditions of the uterus, the fetal head, or an enlarged prostate. As a rule, these lesions are to be found on the anterior wall of the rectum, from half an inch to nearly three inches from the anus. They are not always easy to diagnose, as other foreign bodies or caustics may produce similar appearances. Tubercular and hemorrhoidal ulcers may be mistaken for them; these are, however, generally higher up. A perforating wound gives rise to paraproctitis, but this is not necessarily fatal, though a stricture generally results.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, November 14, 1887.

ROBERT F. WEIR, M.D., CHAIRMAN.

THE first paper for the evening was read by DR. WILLY MEYER, on

NEUROPATHIC INFLAMMATION OF THE KNEE-JOINT (ARTHROPATHIA LABIDORUM).

This affection was first described by Charcot in 1868, and constituted what was known as Charcot's disease. At present its etiology is *sub judice*. The pathological anatomy had been variously described. Most of the cases made their appearance in the ataxic stage of tabes, with sudden onset, without fever or pain, but with morbid crepitation and intra-articular dropsy, with deep anæsthesia, and there was no articulation which might not be attacked. Spontaneous dislocation was not infrequent, especially of the hip and shoulder.

Dr. Meyer presented a patient at the close of his paper, a man thirty years of age, who had never shown any evidence of secondary syphilis, but three years ago symptoms of tabes began. The left knee was involved by the arthropathic disease, and showed the deformity of genu-valgum. There was history of traumatism. The tibio-tarsal joint had also become involved recently. Orthopædic treatment was in operation. The question of resection was raised for discussion.

DR. PARKER SYMS presented a patient from the almshouse, a man apparently sixty years of age, who denied syphilis and had not shown any of its secondary manifestations. Four years ago, after exposure immediately following a bath, he began to feel a weakness in his lower extremities that interfered with walking. There was no disturbance of sensation. Soon after, he had the sensation of walking upon a spongy surface. The joint-trouble appeared last summer in the left knee, where dropsy became marked, attended by swelling of the thigh. There was also considerable thickening of the capsule and the condyles. The man had unmistakable tabes. Although the eyes did not show the characteristic Argyll-Robertson pupil (loss of pupillary reflex to light), there was complete loss of tendon-reflex on both sides and inability to stand with the eyes closed. There was possible atrophy of the optic nerve of the left eye.

THE CHAIRMAN presented a male patient who entered the New York Hospital several months ago on account of

A GREATLY DISTENDED ANKLE-JOINT.

He was fifty-one years of age and without syphilitic history. There was history of articular rheumatism. Six years ago his left ankle began to swell. Prior to that he had had stabbing pains in the legs, staggering gait, inability to walk in the dark, and now has the peculiar, contracted pupil. There were osseous plates on each side of the joint. No other joint was affected.

The man was able to get about quite well with the assistance of orthopædic apparatus, and that mode of treatment would be continued until at least further affection of the joint developed.

The Chairman also presented a specimen which showed the tibia deformed by the osteophytes commonly present in this class of cases.

As to

SURGICAL INTERFERENCE,

the experience of Czerny in six cases had shown it to be unfavorable. His own experience, covering six cases, showed that surgical interference had been rather unsatisfactory, as in all a fistulous opening remained.

DR. E. C. SEGUIN confined his remarks chiefly to some points of fact. First, the rarity of this complication of tabes in private practice. He had never seen a case in his private practice, although he had met with perhaps a dozen in dispensary and hospital patients. Second, the suddenness of the onset and the great rapidity and destructiveness of the process, which spoke somewhat of a distinctive nature of the arthropathy. Third, and also mentioned by the reader of the paper, the occurrence of a large quantity of synovial fluid at quite a distance from the affected joint. In other words, there occurred very early a considerable break in the synovial sac and capsule of the joint.

As to the possible nature of the affection, he was inclined to reject the theory of the essential and specific nervous nature of the arthropathy, and was inclined to agree with Paget that it was a sort of hybrid pathological condition that could be spoken of as

ARTHRITIS IN A TABETIC PATIENT.

He was strongly impressed with the view that it was due to traumatism. Yet, if it was not strictly neuropathic—and the original theory that it depended upon changes in the anterior bone had been abandoned—it possessed peculiar characteristics.

He referred to a case in which he was able to diagnosticate tabes without seeing the patient. It was one to which Dr. Weir directed his attention, with the statement that the knee-joint had become suddenly, and without apparent cause, greatly distended with fluid, and that there was remarkable anæsthesia when the aspirator-needle was introduced. Dr. Seguin suggested that the patient had tabes, and subsequent examination revealed the clinical evidence of that disease. To make the history of the case complete, Dr. Seguin exhibited a microscopic section of the spinal cord of the same patient, that showed the usual lesions of tabes.

DR. M. ALLEN STARR had seen a few cases of Charcot's disease, especially in the Salpêtrière Hospital, Paris, but in a more advanced stage than seen in the cases presented to the Section. Immobility of the joints was the marked feature, and was much more developed in those cases than in the patients exhibited this evening. He agreed with the view that there was

NOTHING ABSOLUTELY CHARACTERISTIC IN THE NERVOUS PATHOLOGY OF THIS JOINT-AFFECTION;

yet the so-called sudden onset might be a mistake. The patient might not be conscious of any pain, but the joint might be fixed by the involuntary contraction of the muscles, and the joint-affection be present for some time without the patient being aware of it until swelling became noticeable.

With regard to effusions, also, a similar theoretical pathological explanation might be advanced. The tendency in a case of inflammation attacking a normal joint was to fix the joint completely, but in these cases the joint was not fixed, and therefore nature provided against injury of the articular surfaces by pouring out a great supply of fluid. Thus might be explained the unusual effusion into the joints in these cases. In other words,

ORDINARY ARTHRITIS IN TABETICS RUNS AN ABNORMAL COURSE,

but that did not imply that there was a pathological process in the spinal cord. There was nothing known with regard to special changes in the spinal cord in tabetics with arthropathy as distinguished from the cases of tabes in which there was no arthropathy.

Degeneration of the peripheral nerves undoubtedly occurred in the course of tabes, yet that as a pathological anatomy of this affection must be abandoned.

DR. J. D. BRYANT would be content to employ orthopædic apparatus until he had become satisfied that the disease had subsided.

DR. R. J. HALL referred to osteoporosis, and asked the neurologists concerning the frequency of its occurrence.

DR. SEGUIN said there was porosity of the bones in tabes, and that it might influence the surgical operation

to be adopted. He was inclined to favor amputation rather than resection; for the reason that the bone was in such a positive state of fragility. Nutrition would probably be *nil*.

Dr. Gerster had seen three cases of arthropathy; two of the knee-joint and one of the ankle-joint. In one case fracture occurred at the upper end of the tibia, where the bone was thickened, and in consequence of a simple trip upon the carpet and fall. That showed that the bone was fragile, but the fragility did not prevent complete union in four weeks.

He believed that exsection was indicated in the first stage. Of course, antiseptic precautions become much more imperative than under ordinary circumstances. Certainly a person could do much better with anchylosis between the tibia and femur than with an amputated limb.

Dr. Meyer was of the opinion that, in the case which he had presented, the bones would unite and the wound heal after resection, and he would advise the operation. The case being in the first stage, it was the proper time for the operation, inasmuch as it should not be performed in the second stage.

Dr. A. M. Phelps then gave a

DEMONSTRATION OF THE OPERATION OF OPEN INCISION IN THE MANAGEMENT OF CERTAIN FORMS OF TALIPES VARO EQUINUS.

The cases to which he applied this operation were those of inveterate relapsing club-foot. The operation was preceded by demonstrations of the anatomical peculiarities of the deformity by means of dissections and casts.

His statistics covered 61 operations upon 36 feet. Of these, 33 were his own cases. In no case had death occurred as the result of the operation.

The wound was allowed to fill with blood, expecting organization of the blood-clot to take place, was dressed antiseptically, and this dressing was covered with plaster. The whole was to be allowed to remain three weeks, and was then to be removed, with the expectation that the wound would be healed, when the position of the foot could be further corrected, if necessary, and a water-glass shoe applied. The aim was to place the foot in the position which would cause the weight of the body to be utilized for straightening it, and the child was allowed to go about.

Relapse was liable to occur, as after all other operations, and hence the great necessity for continuous care until that tendency had been completely overcome.

If the bones were not deformed, primary osteotomy was not justifiable, and no one could tell the amount of bone-deformity present until the open incision had been made.

Discussion was postponed until the next meeting of the Section.

Malignant Tumors of the Kidney are to be differentiated from hydro-nephrosis by the following comparison, given by Ouchterlony:

Renal Cancer.	Hydro-nephrosis.
1. Generally unilateral.	1. Soft.
2. Hard or more than semisolid.	2. Fluctuates.
3. Rarely fluctuates.	3. Liable to suddenly subside at times, with copious discharge of urine.
4. Permanent tumor.	4. Not so.
5. Tumor often of enormous size.	5. Movable.
6. Tumor generally fixed.	6. Descends with diaphragm.
7. Does not descend with diaphragm.	7. More slow.
8. Of rapid growth.	8. Absent.
9. Cachexia.	9. Absent. } Added by Dr. Grant.
10. Hæmaturia.	10. Water. }
11. Blood on aspiration.	

The Prescription of Theine recommended by Dr. East, of Mayo, for hypodermic use in the treatment of neuralgia, is as follows: ℞. Theine, sodium benzoate, āā 3 j.; sodium chloride, gr. viij.; distilled water, f ʒ j. M. Sig.: For hypodermic use. Six minims equal one-half grain of theine.—*Phila. Polyclinic.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ANNUAL MEETING AT THE COLLEGE OF SURGEONS—NOTES AT THE SOCIETIES—STENOSIS OF BILE-DUCT WITHOUT GALL-STONES—SUCCESSFUL OPERATIONS FOR SUPPURATIVE AND TUBERCULAR PERITONITIS.

London, November 5, 1887.

Having an afternoon to spare on Thursday last (November 3d), I wended my way to the College of Surgeons in company with some four or five hundred fellows and members to take part in the Annual Meeting. The occasion was a momentous one, for the council of the college have now actually applied for their new charter. In this the members are simply ignored, and even the fellows are treated with but scant consideration, the only boon vouchsafed them being that of voting for the members of the council by means of voting papers, instead of personally as heretofore. The members and fellows, therefore, must clearly bestir themselves without delay unless they are willing to submit quietly to the oligarchical sway of the four-and-twenty members of the council. They have already taken one important step by presenting to the Privy Council a petition, signed by nearly five thousand members of the college, in which they ask that the additional powers the council are seeking should not be conferred upon them without taking into consideration the claims of the twelve thousand odd constituents of the college. It was unreservedly stated on Thursday that the associations of members and fellows intend to be represented by counsel before the Privy Council, and that, should their appeal to that tribunal prove unsuccessful, they intend to bring the matter before Parliament and the public. Mr. Timothy Holmes opened the attack. He has been a member of the council, and is therefore fully conversant with its methods of procedure. He was also for many years an examiner at the college, and the whole of his speech on Thursday was delivered in that quiet, sarcastic manner before which so many examinees have trembled. He pointed to the enormous number of members of the college, and, by reference to the statistical return published by the council itself, showed that there was not a clear majority of the fellows opposed to some recognition of the rights of the members.

Mr. Holmes commented somewhat severely on the unfair manner in which the circular to the fellows had been worded, and pointed out that if the actual proposals made by the members had been laid before the fellows, the numerical results might have been different. Mr. Holmes then went on to speak of the cool manner in which the council had ignored the request of the members to meet the council to discuss the provisions of the new charter, and here, as in most of his speech, he made his statements specially emphatic by addressing them direct to the council. He said: "*We talk and you act*, and we hoped you would have been kind enough to meet us and really discuss the provisions of this draft of the charter. However, you said you would not do so." Mr. Holmes made a telling point by referring to the clause in the present charter which restricts the college from holding real property of a greater annual value than £2,000, and showing, from the balance-sheet in his hand, that this limit had been largely exceeded. With regard to the policy of the college in excluding the Society of Apothecaries from the conjoint scheme of examination, Mr. Holmes observed: "The General Medical Council most respectfully requested you to reconsider your policy, and the college replied in that highty-tighty, mind-your-own-business style which is so agreeable when applied to other people." Mr. Holmes' speech was well received, and loud cheers rang through the theatre when he resumed his seat. The resolution

he moved was virtually a repetition of that already passed at previous meetings, and rehearsed the grievances of the fellows and members—especially the latter. It was seconded by Dr. Ralph Gooding and carried with only two dissentients.

Mr. Tweedy (Ophthalmic Surgeon to University College Hospital) then moved, "That this meeting respectfully requests the council of the college to transmit a copy of the foregoing resolution to the Lord President of the Council." This was seconded by Dr. Danford Thomas and carried unanimously. Sir Joseph Lister then interposed and intimated that the council would do as they thought proper in the matter, remarking that the individual members of the council must be free to consider the question. The President (Mr. W. S. Savory, F.R.S.) said he would bring the matter before the council at the earliest possible date. I then heard Mr. Ernest Hart's voice calling out, "Mr. President, on a point of order—" and looking round saw his head peeping up over the back row of seats. Mr. Hart (editor of the *British Medical Journal*) proceeded to contend that it was the bounden duty of the chairman of any meeting to transmit to any given authority any resolution passed by that meeting. Mr. Savory ruled Mr. Hart's contention as inapplicable. Dr. Prosser James inquired whether the meeting was not a meeting of the college, and whether, as such, it had not the authority to direct what should be done with any resolution which it had passed. Mr. Savory replied that the meeting was a meeting of the college, but that it had no such authority, and he proceeded to state, amid much laughter, that all power was vested in the council as the executive body of the college. When further asked whether he was the president of the college or the president of the council, he would not answer the question.

The medical societies are now in full swing of work for the winter. Several specimens of interest were shown at the last meeting of the Pathological Society. Mr. Treves showed a specimen of cartilaginous tumor observed in the neck of a little girl. It was not in connection with any fistula, and in this it was unique both in Mr. Treves' experience and in that of the President (Sir James Paget). Mr. Bland Sutton described a fœtus with spina bifida occulta associated with some curious abnormalities. Dr. Sainsbury showed a specimen from a case of Addison's disease in which there was a definite traumatic history. The disease had reached a more advanced stage in one supra-renal capsule than in the other. Dr. Wooldridge showed some specimens of hemorrhagic infarcts of the liver produced artificially by injecting a small quantity of a complex proteid, obtainable most easily from the thyroid body and testicle, but also found in other organs.

At the last meeting of the Clinical Society, Dr. Sidney Phillips read the notes of a case of stricture of the bile-duct which ultimately proved fatal, but in which there was no evidence of gall stones. Dr. Phillips suggested that it was probable, not only that stricture was set up without symptoms of gall-stones, but also that it might arise from causes entirely unconnected with them. Thus stricture sometimes occurred above the cystic duct, and in a position, therefore, where gall-stones would not pass. The absence of symptoms of gall-stones was also a presumption against their having been present, but the chief proof that the stricture was not always due to calculi was, that in some cases, as in the one he had recorded, the mucous membrane was not abraded, and the stricture was formed by contraction of the outer fibrous coat of the duct. Sufficient cases had not yet been reported to decide what causes, if not gall-stones, would produce stricture; but possibly long-continued catarrh might lead to stricture of the bile-duct as gleet led to stricture of the urethra.

Three remarkable cases of peritonitis were then narrated. The first was one of suppurative peritonitis in a man aged forty-two. Mr. Barwell read notes of the case. The patient was admitted into Charing Cross Hospital after an injury. Acute peritonitis followed, and Mr. Barwell opened the abdomen in the middle line below the umbilicus. A quantity of thick pus was found, so the abdomen was washed out with ten pints of warm distilled water, sponged out, and the wound closed without any drain. The peritoneum was seen to be covered with tubercles. Recovery ensued. Mr. Lawford Knaggs then read the notes of a case of tubercular peritonitis treated by laparotomy and washing out. Fifteen months after the operation there was no ascites nor any evidence of the progress of the abdominal disease. The patient—a girl aged sixteen—had gone out to service. She had, however, lost weight, and there was prolonged expiration over the right apex and cessation of the catamenia. Dr. Kilner Clarke then read notes of a case of tubercular peritonitis occurring in a girl aged thirteen. The abdomen was opened and washed out with a one per cent. solution of carbolic acid. Complete recovery ensued, and when subsequently seen the patient was the picture of health, although at the operation the peritoneum was found studded with bodies like boiled tapioca grains. Considerable discussion followed, and one gentleman expressed a doubt as to whether the cases were really tubercular.

THE PESSARY AND ITS SUBSTITUTE.

To the Editor of The Medical Record.

Sir: In Dr. W. Gill Wylie's remarks in The Medical Record of October 8th upon "the abuse of the pessary," it seems to me that his recognition of its inutility in displacements must adapt itself to the experience of a great majority of gynecologists. I did wish, in tracing his article, that the pessary might receive his absolute condemnation save in such incurable cases as call for mechanical support, just as hernia calls for a truss, where it is inexpedient to operate for a radical cure, or where the adoption of other methods with a view to a cure prove inefficient, unpromising, or futile. What ultimate result has ever been attained by the use of this appliance but temporary relief or palliative treatment?—merely a substitution, not infrequently, for more rational, feasible, and curative measures.

No other device, as it presents itself to me, is so prolific of evil, so misguiding and deceptive by its apparent benefit, and so dangerous to the ultimate success of the physician—building up a hope in a false direction, and by its delusion preventing treatment in the right. Temporary comfort is repeatedly bought at the expense of the patient's future health and happiness. Copious leucorrhœa, a congested cervix, granular degeneration of the os, ulceration, and even cancer, are induced by the presence of this instrument—conditions that I have frequently found in patients who proclaimed themselves in a much worse state of health than when they began to wear the pessary. In three instances I have been obliged to sever Hodge's pessary from the cervix, and subsequently to amputate this portion of the uterus, owing to the condition provoked by that instrument. In one instance a section of the os had to be cut away to make the pessary accessible, as it was deeply embedded by tense swelling where it had girdled the cervix.

Any foreign substance in the vagina must have a baneful effect unless it have some property to counteract its evil tendency as an irritant. If it fail in this, it must weaken the walls of the vagina and impair the structures of the womb by its provoking continuous and excessive discharge, thus furthering the progress of the very evil it is intended to cure. Coitus is frequently forbidden—and wisely too—on the ground of irritation by occasional contact, yet it is thought that continuous proximity with a hard, unyielding agent, like a pessary, may be endured with impunity. If, as Dr. Wylie says, "displacement is not a disease—and this is evidently the *rationale* of the premise, for reason points to such symptoms or effects as the off-

spring of a condition or cause that may or may not lie in obscurity—then the indications for treatment are plain. The cause must be removed or the condition improved, and simply aiming our treatment at the effect will never accomplish this object. A few years after I began practice, and after having read of the many brilliant results obtained by the ablest authors and gynecologists by the employment of the pessary, I felt equipped to accomplish wonders in the treatment of prolapsus, but by degrees experience disarmed me of all conceit, and I soon conceived that my resources for success in this direction were as barren as a dead tree. Of course, medicated applications were my only alternative. And these, well selected and properly adjusted, have proved so satisfactory and successful in my employment that I feel I should insult the integrity of the latter method by making a comparison, and after having read the article referred to I feel instructed and further assured in looking to such treatment in displacements for the best results.

F. McTAGGART, M.D.

SAN FRANCISCO, October 16, 1887.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 13 to November 19, 1887.

PERIN, GLOVER, Colonel and Assistant Surgeon-General. Retired from active service, November 17, 1887, by operation of law. S. O. 268, A. G. O., November 17, 1887.

BYRNE, C. B., Captain and Assistant Surgeon. Relieved from temporary duty at Fort McHenry, Md., and will return to his proper station, Washington Barracks, D. C. S. O. 242, Division of the Atlantic, November 11, 1887.

WALKER, F. V., First Lieutenant and Assistant Surgeon. Relieved from duty at Post of San Antonio, and assigned to duty at Fort Ringgold, Tex. S. O. 130, Department of Texas, November 8, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 19, 1887.

RIXEY, P. M., Passed Assistant Surgeon. Ordered to the Naval Dispensary, Washington, D. C.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 19, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	24	7
Scarlet fever	100	13
Cerebro-spinal meningitis	3	4
Measles	52	6
Diphtheria	127	37
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

AINHUM.—Ainhum is an exceedingly rare disease in the United States, and from this fact alone is of more than ordinary interest to the profession. The subject of this affection in the present instance is a very black negro man, tall, erect, muscular, seventy-four years of age, in perfect health, and capable of performing an unusual amount of work, for one of his years, as a laborer on a farm. On removing shoe from left foot the little toe was encircled by a deep sulcus, which had almost completely severed it from the foot, leaving it attached by a small fibrous band, not larger than a large-sized broom-straw. The distal extremity of the toe is globular in form, the nail curved and stunted, semi-elastic and warm to the touch, has no sensibility, and it is impossible to detect any bone in its substance. The proximal end is round, the cuticle much thickened, and has the puckered appearance of a toe which had been amputated by the circular method. There is no bone near the end, but by firm pressure and some manipulation a disk of bone could be felt at the metatarsal joint, rendering intact that articulation. There is no sign of ulceration about the toe. I was very anxious to sever the slight attachment and secure the toe for further examination, but failed to obtain his consent to do so. Three or four weeks subsequent to this time the man, on pulling off his shoe at night, missed the toe, which dropped out of the shoe when he held it up, the separation having occurred without his knowledge. Much to my regret it was impossible to obtain the toe after it had dropped off, as neither persuasion nor argument could overcome his superstitious fears in parting with it. On questioning him repeatedly in regard to the beginning of the affection, he stated that his attention was first directed to a painful condition of the toe when quite a young man, which he attributed to the irritation of a tight-fitting shoe. He distinctly avers, however, that he noticed *then* a slight furrow (as he expressed it) in his toe, which gradually and slowly deepened as the years rolled on; so, according to his account, the disease was in progress for fifty years. Most of the time there was little pain or inconvenience attending it. The greater number of authors who have written on this subject state that it is very slow and gradual in its progress, and that six or eight years is its usual period, no mention being made of its having extended over an interval as long as this case. He could not tell whether other members of his family were ever similarly affected. The corresponding toe of the right foot being absent, I learned on inquiry that it was amputated many years previous to the war by two physicians of this county. It seems that a small thorn had pierced it about midway, and the part beyond the puncture becoming much enlarged and painful, remaining so for several years, and interfering so seriously with his walking, that these gentlemen advised amputation, as the only means of affording him permanent relief. There is scarcely a doubt, from his description of the appearance of the toe, and the long time it gave him pain and inconvenience previous to amputation, that it was a similar affection to that on the left foot. The pathology of this affection is involved in much obscurity, and no definite conclusion has been formed in regard to its true nature. The history of this case would lend support to the view that it is caused by some trophic disturbance of the nerve supplying the part, which has been excited into action by the irritation produced by the thorn and tight shoe.—DR. JAMES EVANS, of Darlington, S. C. ("Transactions of South Carolina Medical Association," 1887).

IODOFORM USELESS IN MENINGITIS.—Apropos of this subject, Dr. Bouchut has published his experience. Dr. Warfinge, it will be remembered, employed this treatment in the case of five children, from three to nine, who exhibited symptoms of tubercular meningitis, with excellent results. Iodoform ointment, of the strength of twenty per cent., was rubbed into the scalp, which was previously shaved, twice a day, during nine days in one case, and during seventeen, nineteen, thirty, and thirty-two days respectively in the other four cases. M. Bouchut states that this treatment completely failed in three cases in which he employed it. In cases of non-tubercular cerebro spinal meningitis, also, it only gave negative results.

THE FAMILY PHYSICIAN OF THE FUTURE.[1]

BY ANDREW H. SMITH, M.D.,

NEW YORK.

THE progress of civilization, constantly opening, as it did, new channels of activity, early rendered specialization necessary in the field of human endeavor. It was found impracticable that anyone should attend personally to all the various claims that his own wants or those of his family suggested, and thus men soon learned to separate the various occupations. At first it was in a broad and general fashion, but as time went on there was a constantly increasing precision, each occupation being divided and subdivided, until at the present time the number of distinct lines of work is almost beyond computation.

Each one of these occupations confers upon those who follow it a certain distinctive position in the public estimation which is apart from their individual or personal character, and which depends upon the usefulness of the occupation and the degree of intelligence and cultivation which it demands.

Quite early in the process of specialization above referred to, the practice of the healing art obtained recognition. At first, and for a long time, it was coupled with other occupations; and it was not until in comparatively modern times that it took an independent position.

It has been, however, long enough before the world to have its position defined, and we will pause a moment to consider what that position at present is.

Tried by the standard we have already mentioned, the usefulness of the occupation and the degree of intelligence and culture which it demands of those who follow it, it should, one would think, command the very highest regard on the part of the general public. Caring as it does for their dearest earthly interests, and devoting to those interests an amount of study and research not equalled in any other profession, it might rightfully expect in return the fullest evidence of appreciation and confidence. But does it receive such evidence? Can it be said that at the present moment medicine holds a place in the public estimation commensurate with the interests it represents? I answer emphatically, no. With all its centuries of faithful and laborious research; with all the devotion and self sacrifice that have hallowed its progress; with all the brilliant discoveries with which it has enriched science; with all the incalculable benefits with which it has blessed mankind, it is still unable to make its voice heard with authority above the clamor of ignorance, superstition, and charlatanry. So far is medicine from being the end of the law in things medical, that the public, even the most intelligent of them, are still ready to lend a willing ear to every new 'ism or advertised absurdity that arises—from infinitesimal doses to mind-cure; from blue glass to "electric brushes;" from liver-pads to anti-vaccination societies. Meanwhile they have been absolutely indifferent to the claims of medical education. While millions upon millions have been contributed to found universities and colleges and libraries and art-galleries and observatories, until within the last decade there has been given for medical schools by those outside of the profession scarcely a dollar. The recent gift to the College of Physicians and Surgeons was so utterly without precedent that men heard of it with incredulity. It is safe to say that more has been contributed to increase our knowledge of the stars, millions of miles away from us, which cannot influence us and which we cannot influence, than to increase our knowledge of disease, which takes its seat at our fireside, and which, on the one hand, may desolate the home, or which, on the other, science may baffle or expel.

The public look on with indifference while a young man is struggling and starving to obtain his medical education with facilities which, meagre as they are, are yet to be paid for at every step; and when at last his degree is obtained, they generously allow him to serve in their splendidly endowed and often palatial hospitals for nothing.

The hospitals themselves, though dependent upon the profession to carry out the objects for which they are organized, do not invite medical men to take a share in their management. Of the forty-seven hospitals, great and small, in the city of New York, only two, so far as I have been able to learn, have medical representation in the board of directors.

To look after the public health would seem to be peculiarly the duty of the medical profession, and the idea of a *board of health* that would first occur to everyone would be that of a body of men selected by the profession to put into practice the principles of public sanitation. Yet for this city the fact is that the profession has no voice whatever in the selection, and, furthermore, the law under which the board is organized specifically provides that it shall not be presided over by a medical man. And until recently the attitude of the board toward the profession has been that of master rather than coworker. Instead of drawing its inspiration from the profession, it has classed the doctors with the plumbers, tenement-house owners, bone-boilers, etc., as persons to be carefully watched and sharply admonished lest they should fail to obey some mandate of the power above them.

Another evidence that medicine does not hold its legitimate position is to be found in the fact that medical knowledge, however extensive and profound, does not give its possessor a corresponding position in the ranks of learning. Almost any other pursuit requiring similar qualifications may claim precedence. This is strikingly shown in the recent distribution of jubilee honors in Great Britain. A successful lawyer is known throughout the length and breadth of the land, and his opinion is asked and his aid sought in all matters of public interest. The same may be said of men eminent in theology, in literature, in science. Their reputation is general, and they are looked up to as natural leaders, those who are to give direction to public opinion. But, with few exceptions, the medical man, however eminent, is known, except by his own profession, only in the vicinity in which he lives, and even within these limits his reputation is strictly professional. No one ever thinks of looking to him for anything more than a diagnosis and a prescription, or perhaps to hew off a limb, or cut out a tumor. And from this it results that the profession as a whole exercises an unimportant influence in the community, and takes but little part in the conduct of public affairs.

And yet the training of the medical man and the di-

[1] Annual address before the New York Academy of Medicine, Nov. 17, 1887.

rection of his mind are, or ought to be, such as to make his influence in secular affairs more valuable than that of any other member of the community. For however eagerly we may pursue the various vocations in life, the ultimate consideration which dominates every other is the prolongation of life and the preservation of health. It is true that this consideration often seems to be disregarded, but it is only because men do not appreciate the risk they are running. No one in his senses ever knowingly and deliberately places any other object before it. In comparison with it considerations of wealth, fame, power, influence, all sink into insignificance. Surely, then, if the profession which is charged with such grave interests reached out into all the avenues of life, and laid hold of everything that directly or indirectly influenced these interests, it would stand before all otner secular callings, and command universal attention, respect, and co-operation.

But its failure to take this position finds its explanation precisely in the reservation I have just made. Medicine has not appreciated the extent of the field it was its province to occupy, and, accepting an inferior rôle, has suffered a corresponding loss of position and influence. The very name it bears, the Science of Medicine, is derived from only one of the means employed in its practical application, and sufficiently indicates the narrowness of conception to which I refer. There is too much of a disposition to restrict its field simply to the relief of disease already present, without taking note of the broader and higher mission which it should aim to fulfil. The science of medicine is but a fragment of the far greater science which has for its subject the physical well being of mankind; and it is because this fragment has received such exclusive attention, and has yielded results so much less beneficent than might have been attained by a more comprehensive reach, that medicine has failed to win its proper place in the respect and confidence of the civilized world.

Both as a science and as an art it has occupied itself too much with the individual organism, and not enough with that organism in its relation to other individuals and to the race in general. As a pure science it has limited its investigations too much to the normal and pathological phenomena of animal life, and as an art it has sought only to relieve the present suffering of the individual and to prolong his life. It has left almost unnoticed the great questions of the influence upon the physical well-being of the race which is exercised by heredity, by race-peculiarities, by climate, by occupation, by social habits, by the distribution of wealth, by laws, by commerce, by education, by literature, by architecture, by religion. On these and kindred topics there has been almost no systematic effort to obtain, preserve, and collate information; the nearest approach being the statistical tables published by boards of health, which, being based upon defective data, are misleading in proportion as they claim to be exact.

These matters are practically ignored in the teaching of our medical schools, though a few of these nominally have a fraction of a chair devoted to Public Medicine.

But if medicine is ever to take its proper rank, the first step must be a remodelling of the relation of the family physician to the families under his charge. I say the family physician, for there is such a phrase current in the mouth of the public, although it has much less meaning now than formerly. There was a time, before the spirit of change became dominant in this as in everything else, when the family physician was a reality, however imperfectly he may have represented the ideal which I believe the family physician of the future will attain. But his field, instead of widening, has contracted on every hand, until, in the cities at least, there is now scarcely standing-room for him remaining. I say this without personal bias, for I am myself on the borderline between specialism and general practice.

Many a New York lady, if asked what she meant by her family physician, might reply truthfully as follows: "Our family physician is the doctor we are in the habit of calling in when we don't know what specialty the case belongs to. We have Dr. A for the eye, Dr. B for the throat, Dr. C for the heart and lungs, Dr. D for the nerves, and Dr. E for gout and rheumatism, and when one of us is sick and we don't know how to classify the trouble, we send for our family physician, Dr. F, to tell us."

This is scarcely an exaggerated picture of the relation of general medicine to the public, and we may well inquire what influence, under such conditions, it can be expected to exert in the community.

For medicine can be a power in the world only as it is represented by the general practitioner. The specialist operates along a single line, and the lines of the several specialties are ever divergent. Moreover, specialists are occupied with a constantly changing *clientèle*, and lack entirely the opportunity for continuous influence. They cannot impress themselves or their calling upon patients whom they see to-day and lose sight of to-morrow. And further, being concerned only with the relief of existing disease, they take no cognizance of the broader field already alluded to, which it is the proper province of medicine to occupy. It follows, therefore, that in proportion as the specialties acquire an independent position, and the specialist breaks away from the family physician, medicine as a whole becomes restricted in its scope, and suffers a loss of respect and influence. We cannot bring our profession to the highest point of usefulness, and thus secure for it the commanding position which is its due, by resolving it into a multitude of independent and, in a degree, rival factions.

The aid of specialists will always be required, for the field of medicine is so vast that no one can become expert in all its branches. But the time will come when this aid will be rendered only at the instance of the family practitioner. The practice, now so common, of going directly to the specialist, or perhaps of consulting several specialists at the same time, will be given up. The oculist, the dermatologist, the gynecologist, and the nerve-specialist will not each at the same time be carrying on an independent line of treatment for the same patient, the measures adopted by one perhaps neutralizing those adopted by the others. But the aid of each will be invoked in its proper course by the family physician, who will possess such a general knowledge of all the specialties as will enable him not only to know when they can be usefully employed, but also to direct their application in reference to each other, and in accordance with the general condition of the patient.

The tendency of modern research is to give especial prominence to preventive medicine. The revelations of the microscope during the last decade have taught us many impressive and valuable lessons in the prevention of disease, while they have scarcely afforded us a single practicable suggestion as to cure. The triumphs of antiseptic surgery lie much more in the direction of keeping germs out of the system than of expelling them after they have effected a lodgement. And this is, beyond doubt, typical of the line in which medicine as a whole is to have its principal development in the near future. And it is this, too, which will command the attention of the laity, and win their confidence. As a consequence, instead of relying upon this or that method of cure in case they should become ill, men will prefer to put themselves under such direction as will tend to avert illness. And this will be the chief province of the family physician. To relieve suffering is a godlike office, but to prevent suffering is a higher office still. The good Samaritan rendered a service that shall be a proverb for all time, but if the traveller had journeyed from Jerusalem to Jericho in the company of a Roman soldier the tender ministry of the Samaritan would not have been required.

But to this end there will need to be a more thorough

identification of the physician with his families, the establishment of a more intimate footing, which will make the doctor the counsellor in every matter in which the health or physical well-being of any member of the family could possibly be involved. As the family solicitor in England is familiar with the minutest detail affecting the estate, and is consulted before even the least important step is taken, instead of only being called upon to conduct an occasional suit or to draw up now and then a legal document, so the family physician should be the sanitary adviser, having constant supervision of the family health, instead of being called in only when someone has broken a leg or one of the children has the croup.

But this implies, to begin with, that the position of the family physician shall be more distinctive and more permanent than is now the case. At present the bond is barely recognized, and, having no basis of obligation, is liable to be dissolved at any time for the most trivial cause.

1. On the practical assumption that the function of medical skill is to cure disease, not to discover and ward off its approach, the physician is seldom afforded an opportunity to apply his art until disease is not only present, but has progressed so far as to alarm the patient or his friends. The question of the necessity for treatment is thus decided, not by an expert, but by those not qualified to determine the meaning or the gravity of the symptoms. This may be unavoidable to some extent in acute disease; but how often it is that we see a case of chronic kidney affection only after dropsy has developed, or one of pulmonary consumption after the cough has continued for weeks or months and has excited alarm by its very persistence. If medical skill is of little avail under such circumstances, the fault is not so much in the art as in the conditions under which it is practised.

But this is only the beginning of the evil which comes from regarding the physician as one to be consulted only when the patient in his unskilled judgment considers it to be necessary or advisable. It results that, except under such conditions, the proffer of advice by a medical man, or even an earnest inquiry as to health, would be considered an intrusion. Advice not asked for is seldom welcomed; the search for information on many important points beyond the immediate case of illness would be resented as an impertinence. The physician is thus kept at arm's length, and, as a rule, does not obtain that intimate knowledge of the family antecedents which would fit him for discharging the full duty of his office. Called, and too often dismissed, at the discretion of the patient, he feels that the bond between them is an uncertain one, and naturally his interest is limited in a great degree to the present illness, without extending to that constant care and oversight of the family which alone can give the best results.

And as is his practice so is his preparation. The information required at the bedside is all that the average doctor troubles himself to acquire. To recognize disease and to apply the remedies for it is to his mind the extent of his office, and to attempt more than this, which is all that custom demands, would seem to him a work of supererogation.

Manifestly, so long as this continues to be the relation of the medical man to his families, the relation of medicine to the public cannot be expected to improve. The man who sees in his family physician only a feeler of pulses and a writer of prescriptions will not be likely to see in medicine an influence to be invoked with confidence in a large variety of matters affecting the public welfare. Hence the voice of the profession will be unheard in the halls of legislation except in the timid utterance of worn-out platitudes about epidemics and quarantine and laws against quackery. Its influence will not make itself felt in a virile grasp of the great principles that underlie the physical well-being of society. Neglect of public sanitation will continue to fill our hospitals and our cemeteries; architecture will continue to be the handmaid of disease; systems of education arranged without the slightest reference to the laws of mental development will continue to overtax and distort the minds of the young. Questions of health will not have their weight in determining the relations between capital and labor; excessive hours of duty, exacted from those to whose vigilance the lives of the travelling public are intrusted, will continue to result in appalling disasters, which coroners' juries will continue to ascribe to every cause but the real one. Unrestricted traffic in drink will continue to destroy health and life in the present generation, and to prepare an inheritance of disease for offspring yet unborn. Public opinion will continue to applaud, if not to demand, that abnormal activity in business and in social life which has already gone far toward making us a nation of invalids, and, judging from the statistics of our asylums, promises to make us a nation of lunatics.

Against these and many other influences affecting injuriously the physical, and through it often the mental, condition of vast masses of people, who are our natural protectors if not the medical profession? Who is to speak for better things if they remain silent? Is it the clergy? Four-fifths of our people, alas! never come within their reach. Is it the business-men? As a class, with many honorable exceptions, they are too busy to attend to anything which does not make a showing on the ledger. Is it the professional philanthropists? What practical good has ever been effected by their vagaries? Is it the politicians? Heaven save the mark!

No, if anything is done in the direction I have indicated, it will be the medical profession which will have to take the lead.

Descartes has said: "If it be possible to perfect the human race, it is in medicine that we must seek the means." While not anticipating the perfection to which he refers, we may well believe that whatever progress is made toward it will be worked out essentially through the agency which he indicates.

But, to return from this digression, what in detail is to be the character of this improved relation between the medical practitioner and the families under his charge? I can best illustrate my view of this by taking up the life of a young married pair, and tracing step by step the position which their medical adviser should occupy toward them as the family life develops.

In the first place, this medical adviser should be selected with the greatest care, and with reference to his practical knowledge and sound judgment. He should not be too much their senior, for it should be no part of their plan to change without the gravest reason; and the doctor should be young enough to continue in his position, in the natural order of things, for the greater portion of their lives. They should then begin by placing before him the medical history of each as completely as it can be obtained, together with all the facts they possess touching the medical history of their immediate ancestors. This information should constitute the beginning of a minute and careful record to be kept by the physician and transmitted to his successor. This record should contain the results of a careful physical examination, so that the state of health of each one shall be known from the beginning. These examinations, as thorough and exhaustive as those required by the most careful life-insurance companies, should be repeated at stated intervals and duly entered upon the record. It should be impossible that the first manifestation of a detectable chronic affection should be by a disastrous explosion. Sudden death from *unsuspected* heart or kidney disease, for example, should be relegated to the traditions of the past. There should be no more histories like the following: A gentleman who at most has had only an occasional headache, or a passing nausea, a mere trifle which he would scarcely mention to his family, goes in the morning to his place of business. A few hours later, a carriage stops before his up-town residence;

he is lifted out in a state of insensibility and carried to his room; a physician, anyone who can be found, is hastily summoned; vigorous treatment is resorted to at once, but without avail; consciousness does not return; and death takes place within a few hours from uræmia. He never suspected that he had Bright's disease, yet a very simple examination would have revealed the fact to his physician, and proper treatment would have averted the catastrophe, if not wholly, at least for a lengthened period.

Or, again, a person while walking rapidly in the street, perhaps hurrying to catch a train, sinks down, gasps a few times, and is dead. A coroner's examination reveals that which neither he nor his family were aware of, that he had fatty degeneration of the heart. Yet the suspicion of the doctor would have been excited if he had only laid his finger on the pulse, and his ear applied to the chest would have confirmed the suspicion. Thus forewarned, proper care and an appropriate regimen might have saved life for many years.

A persistent quickening of the pulse may be for a considerable time the only symptom of Basedow's disease, the affection not coming to the notice of the physician until the enlargement of the neck and the protrusion of the eyeballs have attracted the attention of the patient. Treatment begun at the earliest moment that a diagnosis is possible would doubtless give better results than we usually obtain.

An overworked brain gives out signals of distress which are intelligible to the physician long before they attract the notice of the patient. When the patient himself is able to make the diagnosis, mischief has been done which may be irreparable.

Oculists and aurists will probably agree that a large proportion of the serious cases which come before them are made serious by neglect, and that this neglect arises from the disease not being recognized in its early and curable stage. In fact, it might be said of all the specialists, that they thrive upon the shortcomings of the general practitioner. But for these shortcomings the family doctor is not so much to blame as the system, or rather want of system, under which he has to labor. When a child has lost the use of one ear, the parents suddenly discover that he is a little hard of hearing. Treatment may now be of no avail, whereas, if the hearing had been tested by scientific methods a year before, the first indications of the defect would have been apparent, and the disease might have been easily arrested.

What seems to be only a common headache is often the precursor of a disturbance of vision not yet appreciable to the patient, and permanent injury to the sight may result before the eye is thought of as the seat of the trouble. Here, as in the case of the ear, periodical examinations would lead to early detection of the trouble, and perhaps to successful treatment.

How seldom it is that the physical condition of a person not consciously ill is made the subject of investigation. Yet the experience of examiners for life insurance, on the one hand, and the frequent occurrence of examples such as I have just related, on the other, show how often chronic disease remains for a long time undetected, and what peril to the patient the failure to detect it may occasion; all of which would be guarded against by periodical examinations, duly recorded.

At the birth of each child every important circumstance connected with the event, as also with the subsequent lactation, should go upon the record. The progress of dentition; the age at which the child walks and talks; the closure of the fontanelles; the particulars of the vaccination—all should be entered in due order. The occurrence of one of the contagious diseases of childhood should be the subject of especial care in recording. The source of contagion; the period of incubation; the character, intensity, and duration of the eruption; the complications, the treatment, and the sequelæ—each should be carefully noted.

Once a year, or more frequently, the height of each child and the weight of each member of the family should be entered upon the record.

And here let me pause for a moment to dwell upon the advantages which would result from the general adoption of the plan of preserving in this form the medical history of each member of the families under our care. The value of such a record to refresh the memory of the family physician, or to inform those who are to succeed him, is at once apparent. Our judgment of the present is very greatly influenced by our knowledge of the past. For example, the significance of a heart-murmur discovered in adult life would be much more grave if the record showed that the patient had suffered in childhood from rheumatism with heart-complication. A chest-affection would be much more likely to be tubercular in a subject who had shown signs of struma in infancy, and so on. But, in the absence of a permanent record, our knowledge of the past history must have all the vagueness of memory or tradition, and, in any case, a few years will suffice to blot it out entirely. Thus we lose also in a great measure the advantage of the experience with the individual patient which would enable us to take count of idiosyncrasies. No two people respond alike to treatment, and general principles have constantly to be modified to suit individual peculiarities. It is by becoming "acquainted with the constitution of the patient," as the phrase goes, that we learn to prescribe for him most satisfactorily. Without memoranda, to keep up this acquaintance is difficult, and to transmit it to another is impossible.

But the value of such a record would not end with the subjects of it. The next generation would profit by it perhaps as much as the present. Heredity is an influence the power of which it is difficult to estimate, for the very reason that the absence of such records as I propose prevents our tracing it backward in the family history. With such a record, however, we should know from the history of the parents what to expect in the children, and the timely use of precautionary measures might avert a great deal of suffering and disease. Dr. Holmes has said that the proper time to begin the treatment of some diseases is a hundred years before the birth of the child.

But aside from the direct and immediate usefulness of such records, their value for *scientific* purposes would be inestimable. If the system were generally adopted, the mass of recorded facts open to scientific research would be enormous. Every practitioner would be enabled, in the course of years, to settle from his own experience many a disputed question of great importance. The time of society-meetings and the space in medical journals would no longer be occupied by the "impressions," and "convictions," and "opinions" of the different speakers and writers, but solid, tangible fact alone would be allowed a place in medical discussion. Upon every question that arose light would be poured from thousands of records, and the science of medicine would advance more in a decade than it does now in half a century.

Such records would differ materially from case-books as the latter are usually kept. In the first place, they would not be limited to "interesting cases," but would take in everything, and no one can tell what importance the most commonplace note may not one day assume. In the second place, the keeping of the record not being simply for the benefit of the doctor himself, but a recognized obligation toward the patient, the work would be faithfully performed. The question of the expenditure of time required will be referred to as we proceed.

But to go back to the point from which we digressed. As each child grows older, nothing that can have an influence, present or prospective, upon its physical condition should escape the scrutiny of the doctor. The food given it, the clothes it wears, and the habits it forms, should all come under his observation. Even

parental discipline should be open to his criticism, the timid and nervous child being screened from harsh rebuke, while, on the other hand, the evils of good-natured indulgence on the part of the parents are pointed out. They should be made to understand the supreme importance to the future health of the child of making obedience the first habit to be acquired; and also that this can be done without the least harshness, by beginning at the first moment of intellectual consciousness. Many a child's life is sacrificed by the opposition of its untrained and untamed will to the means necessary for its relief in sickness. Brute force applied to a sick child is a terribly poor substitute for the gentle yet absolute control which the habit of unhesitating obedience places in the hands of the parents. And not only so, but the vigorous means which may be thought necessary, as the child grows older, to break its will and to enforce parental authority, may have quite as bad an effect upon its physical and mental health as upon its moral nature. Young parents are not apt to realize this, and they will bear to have it pointed out to them by their doctor, when they would resent the admonition if coming from any other source.

When a child begins its attendance at school, it should be the duty of the physician to know, from personal inspection or from some other trustworthy source, that the school-room is in a good sanitary condition and properly warmed and ventilated. He should familiarize himself with the sanitary history of the principal boarding-schools within reaching distance, and should have a voice in the selection of such as are to be patronized by his families.

Putting himself in correspondence with a local practitioner in whom he has confidence, he should inform him of the peculiarities and susceptibilities of each child whom he transfers to his charge. He should observe from time to time the effect of school-work upon each one, and should insist upon a modification of the course whenever demanded in the interests of health. In order that he may do this intelligently, he should make himself familiar with the general laws regulating the successive development of the different mental faculties, and should note any deviation from these laws in the children under his charge.

If this supervision were properly carried out, we should not see children with delicate lungs sent to boarding-schools located in bleak and exposed situations, nor those susceptible to malarial influences sent to the vicinity of marshy grounds or stagnant water. The subject of repeated attacks of tonsillitis or quinsy would not be left to the chance of having an attack culminate before the local physician should become aware of the susceptibility. The perplexity of the latter regarding a doubtful eruption would not be increased by uncertainty as to whether the child had had, or had not had, one of the contagious diseases of childhood. A boy with impaired heart-valves would not be allowed to join an athletic club, nor one having a strong hereditary tendency to hernia to take part in a rowing-match. A pupil, perhaps not near-sighted himself, but one or both of whose parents were myopic, would not be allowed day after day to do drawing or to read fine print with insufficient light. And most important, perhaps, of all, children would not be set at tasks requiring abstruse reasoning or subtle analysis at an age when the *memory* is almost the only faculty capable of acting; nor would the same studies be forced upon one child whose faculties developed in a certain order, and upon another child whose faculties developed in a totally different order. The stolid, pachydermatous child and the timid, sensitive, highly organized one would not be subjected to the same cast-iron methods.

And so on, in a thousand ways, the influence of the skilled judgment and the wise counsels of the physician would be felt all through the educational course of each one of the children; and, furthermore, if every child, or even a part of the children in each school, were known to be under the watchful eye of a competent medical man, the schools themselves would soon be changed for the better in many essential particulars.

When the time came to decide upon the occupations of the boys, the advice of the doctor should go far toward fixing the decision. He should not allow a narrow-chested, ill-nourished youth, with a strumous record, to be placed behind a desk in a close, dark, ill-ventilated counting-room, where the consumptive tendency would certainly be developed; nor a young man with a highly nervous organization, and coming from a highly nervous stock, to be exposed to the brain-wrecking excitement of Wall Street. The railroad magnate, long since diabetic from excessive mental strain, should not be encouraged to make his son his prospective successor in office, with the prospect of succeeding also to his disease.

In like manner the girls should be protected, so far as possible, from those influences which make so many women of the present day such wretched caricatures of true womanhood. Moreover, if, in the case of one of the daughters, the record showed late development of the teeth and late closure of the fontanelles, together with other indications of defective deposition of bone, everything looking toward marriage should be discouraged, until it was ascertained positively that no bar to maternity existed.

The domestic habits of the family should be considered proper subjects of the doctor's criticism. He should at all times be a privileged guest at the family board, and should feel at liberty to comment in a delicate and proper manner upon any unhealthful habits or methods which he might observe. What the man is to be is often determined by what the child eats; and with older persons the selection of food, and the manner of taking it, often make the difference between health and invalidism. The practice which allows the head of the family only the shortest possible time to force down a hastily prepared and unattractive meal before going to business, while it permits the daughters, half attired and half awake, to straggle into the breakfast-room at any time before midday, is as much opposed to sanitary principles as to the proprieties, not to say decencies, of domestic life.

The social custom according to which, night after night, the young of both sexes give up a large portion of the night to revelry, is responsible for an enormous sacrifice of health and life. That this custom continues in this enlightened age is sufficient proof that, though the school-master is abroad, the doctor is not. If the medical profession exercised the influence which the nature of its calling implies, rational beings would adopt more rational methods of enjoyment.

The same argument applies to the subject of dress, and particularly to the dress of women. The future student of history, when reading of the social customs and dress of the nineteenth century, will surely exclaim, "Were there no doctors in those days?" And the more advanced student will reply, "Yes, there were plenty of them, but they had very little influence in the community."

In the selection of a new residence, the first step would be to consult the physician as to the healthfulness of the location and the sanitary condition of the premises. These questions would be decided upon much broader grounds than the dictum of a self-styled sanitary engineer—grounds which would include a knowledge of the past and present topography of the region, as well as of the sanitary history of the proposed residence. For example, a site would not be selected where a water-course had been filled in with refuse and garbage, nor would a house in which a consumptive had lived, even years before, be occupied without thorough cleansing and renovation. Even in temporary removals, such as are made each summer, the advice of the doctor would be sought; and it should be a part of his duty to acquaint himself with the peculiarities of the principal resorts, and to know, and to be in professional correspondence with, the best qualified of the resident practitioners. The

many cases of autumnal typhoid contracted at the summer watering-places, and developed after the return to town, sufficiently attest the necessity for this supervision.

This is but a partial sketch of what I believe will yet be considered the duty of the family physician. I might go much further into detail, but enough has been said to show what a large field is open, and what a different position the profession of medicine would occupy if it entered into this field and did all that it might do for the benefit of its clients. It may be objected that much that has been indicated is what intelligent persons ought to be able to do for themselves. Granted, and yet the fact remains that it is not done, or even thought of, until bitter experience has taught the lesson which might have been more humanely imparted by the physician.

It is evident that the expenditure of time required for this service would be very great, and it would be quite impossible to carry it out fully by the methods now in use. A physician could not have an unlimited number of families on his list, for it would be understood that there was a certain amount of constant work to be done for each family irrespective of sickness. He would render the same amount of service as at present, but it would be rendered to a smaller number of persons. When his list comprised the number of families to which he could do full justice he would refuse to add to it. There are many competent physicians—the cry is that there are too many—but there would be occupation for all if none of the work which should be done were left undone. Indeed, the plan implies that each doctor in full practice should be training a younger man to divide his labor, and ultimately to become his successor.

But doctors, like other people, must live, and the question will be asked: How can the family physician afford to do this increased amount of work and to cut down the list of his patients as suggested? The answer to this is, that when the public comprehend the full scope of the doctor's work, this work will, if faithfully performed, bring greater respect and increased emolument. Let once the idea be grasped that the physician is engaged in preventing disease instead of waiting for an opportunity to cure it—that his mission is a wider one than merely to deal out pills, or open abscesses, or attend confinements—and the dignity and importance of his office will be increased in the public estimation, and his services will be more highly valued and more liberally rewarded. Why should a lawyer, for services that involve only property, be paid ten times the fee that the physician receives for services that involve life? It is partly, at least, because the client, in the first case, can appreciate and follow the work that is being done for him, while the patient, in the second case, cannot.

But the extra work of which I speak would be such as the public could thoroughly comprehend, and they could judge for themselves of its value. It is one thing to pay out money which represents merely certain prescriptions written, the effect of which may not have been obviously beneficial, and quite another thing to know that the semiannual check includes the recognition of a watchful care and a skilful oversight that have surrounded the whole household with a protective influence.

It will be inferred from this sketch of his duties that the family physician of the future will need to be a man of varied culture and great learning, of deep sagacity and sound judgment. He will need to know much more than how to make a diagnosis or to write a prescription. He will have daily use for more, and more varied, knowledge than any other man in the community. His preparation will require as its foundation a thorough preliminary education in lines that will give the greatest development to the reasoning faculty, for a man cannot become a good physician by studying medicine only. He will need to be trained to view a question from all points, and take account of everything that may throw a side-light upon it. He will require a detective's quickness of perception, a lawyer's skill in weighing evidence, a business-man's method and system, and a clergyman's self-abnegation. His professional training might well omit a great deal that now occupies time and yields no practical result, while it should embrace much that never yet has entered into a medical curriculum. To the higher education of which we hear so much in medical circles, should be added the broader education of which we hear comparatively little.

Upon the correctness of his conclusions will hang the weightiest interests. He will need to have the courage of his convictions, and to be willing to go counter, when needful, to the current of public opinion. While he will have warm friends, he will have bitter enemies also; for his influence will be opposed to many schemes of selfishness and greed. Wealth will not flow into his coffers; in fact, he will need no coffers, for his wife's milliner will probably have an income larger than he. Yet, withal, while having ten or fifteen years of vigor still before him, he may be able to retire, leaving the active duties of his profession to be carried on by his associate under his supervision. He will then have leisure to take a more active part in measures of public benevolence, and especially in matters relating to the public health. In the governing boards of institutions, in municipal affairs, in the state and national legislatures, his influence will be felt for the common good. His pen will be a ready agent in framing public opinion in favor of liberal action in all matters of substantial sanitary reform. The burdens which rest upon the poor, making healthful living almost an impossibility, and the self-imposed burdens which produce nearly the same result upon the rich, will alike engage his efforts toward practical amelioration. In short, under all circumstances and in all positions, he will so represent the higher and broader aims of medicine as to give the profession a standing before the world commensurate with the dignity and importance of its office.

This is more than an ideal sketch; it is a prophecy, which I believe will yet be fulfilled. Indeed, there are many signs that it is already in process of fulfilment—signs that I cannot now enumerate, but which are full of promise. But to its complete realization both the profession and the laity must contribute. The tendency of the former is to increased effort; will the tendency of the latter be to increased confidence and co-operation? I believe it will. As men grow older they tire of the aimless occupations of earlier life, and seek that which gives substantial good in preference to what amuses or entertains. So as society grows older it learns to distinguish between the froth that floats on its surface and the deeper current that carries with it all that is of substantial benefit to mankind. Thus that which contributes most to the general welfare will receive most of public recognition; and when medicine assumes the full obligation which rests upon it, when it enters upon the broader field that awaits its occupation, when it prepares itself to grapple with the remote causes of physical imperfection as well as with present disease, then it will command the veneration of the world as the highest of earthly callings.

And now, a word in conclusion in reference to this Academy. The past few years have been a period of remarkable prosperity. They have witnessed a vast increase of membership, of activity, and of material support; and the near future has promise of greatly improved facilities and of enlarged usefulness. Let us determine, then, that the Academy of the future shall be like the physician of the future, the representative of medicine in its largest sense, in its fullest development; that its voice shall be heard wherever an influence exists which militates in the slightest degree against the highest physical perfection of the human race; that it shall be to the community what the family physician will be to the family, the sanitary guardian, bearing ever in brain and heart a wise and watchful and tender care for the interests confided to its keeping.

A HUGE FIBROMA OF THE ABDOMINAL WALL SIMULATING AN OVARIAN TUMOR —LAPAROTOMY—RECOVERY.[1]

By ROBERT F. WEIR, M.D.,
SURGEON TO THE NEW YORK HOSPITAL.

The diagnosis of the present case was only made out after the operation had been completed. The patient was a married woman, aged forty-one, childless, and who four years ago noticed that the lower and central portion of the abdomen began to enlarge. This continued, with but little pain and with occasional attacks of dyspnœa and bleeding piles. There has been no menstrual disturbance. She has, however, within the last six months lost a good deal of flesh and deteriorated decidedly in strength. During this time the tumor has apparently doubled in size. She now measures thirty-five and one-half inches around the level of the umbilicus, and presents the usual appearance of a woman with a large abdominal tumor. The growth varied in consistence, was hard and irregular particularly to the right of the median line, and gave a faint wave on percussion at its upper portion and toward its left side. Its edges could not be defined, but the swelling seemed to reach nearly from one iliac spine to the other, and extended a hand's-breadth above the umbilicus, where it was only recognized by sudden and deep pressure. The uterus was small and freely movable. The ovaries could not be felt. It was supposed to be a multilocular ovarian tumor, and possibly of sarcomatous origin. Her urine was free from albumen and sugar, and the urea amounted to four hundred and fifty grains per diem, which, according to Thiriar, would lead to the belief of its benign character.

On Tuesday, November 1, 1887, an abdominal incision, running from the umbilicus nearly to the pubes, was made under ether, using Tait's method of cutting the tissues when coming near the peritoneum, between two forceps, and thus lifting up the peritoneum, but the latter membrane was not recognized until the wall of the tumor was reached. It was then thought that adhesion had occurred between the anterior wall of the tumor and the parietes, and a cautious endeavor was made to separate the same, first laterally and then upward; but though a membrane could, in the latter direction, be easily stripped off from the tumor, yet the hand so doing this was carried, while following the tumor, backward from the abdominal walls. This membrane was everywhere adherent, with fine, easily yielding cellular tissue, but with no gaps through which intestines or other abdominal viscera could be felt. Feeling assured I was beneath a membrane covering the tumor, though yet puzzled as to what I had to deal with, I desisted from the stripping process and enlarged my wound upward beyond the umbilicus until the peritoneal reflection from the tumor was reached and the cavity of the abdomen opened, when manual exploration revealed that I had to deal with a huge tumor covered posteriorly by peritoneum, and projecting into, and fully occupying, the upper pelvis. Its attachment was not yet determined, and this point was only decided after the mass had been with some difficul y forced out through the seven-inch incision of the abdominal walls. Then the lateral peritoneal reflections were divided to nearly its lower level, when its supposed pedicle, then thought to be the broad ligament, was clamped and divided on the right side, which allowed the whole mass, yet attached in front and on the left side, to be enucleated and removed, with but moderate hemorrhage from two or three large veins, which were seized and tied with catgut. The lower pelvis then came plainly into view, the intestines being completely empty, and the uterus and its broad ligaments, and both ovaries, were found in a normal condition. A closer inspection now showed that the tumor was an extra-peritoneal growth, and that, had I known its nature, it would have been possible to have continued my stripping-off procedure and to have removed it without opening the peritoneal cavity. A sheet of peritoneum, equal to the extended two hands, and situated on the posterior surface of the tumor, was taken away with the growth; the surplus of this membrane, which had been caught in the clamp and which remained on the left side of the abdominal incision, was now trimmed away, the slight hemorrhage controlled by catgut ligatures, and the cut edges of the serous membrane sewn together as in an ordinary laparotomy. On trying to gather up the transversalis fascia to join the edges of this by separate sutures, as Wylie advises, to prevent a subsequent hernia, this membrane could not be found, and this fact suggested the possible origin of the tumor. For the nature of the growth was, as reported by Dr. Peabody, the pathologist of the hospital, mainly of pure fibrous tissue, with, in various portions of it, some few muscular fibres. The weight of its solid parts was over eleven pounds. To this must be added about two pints of clear yellow fluid that escaped from two large trocar-punctures that were made in a vain endeavor to diminish its size, making thus a weight of nearly fourteen pounds. It was nearly spherical, and its circumference measured twenty-four inches. The subsequent steps in closing the wound were as usual, save that rubber drainage-tubes were introduced from the lower angle of the wound into the lateral pockets which had been created by the enucleation of the inferior part of the tumor. The progress of the patient, so far, has been without any reaction.[1]

Such growths, though generally of smaller size, have been met with by other surgeons and gynecologists. I have been informed by Dr. T. G. Thomas that he has encountered four similar to the one just described, and which he has made the subject of a paper to be shortly published. Czerny speaks of one, and Heineke, of Erlangen, in his article on "Entzündungen, Anschwellungen und Geschwülste des Unterleibes," describes[2] a number of tumors—fibromata, fibro sarcomata, and myxo fibroma—which are developed from the muscles, aponeuroses, and fasciæ of the abdominal walls. He calls attention to the posterior wall of the rectus and to the transversalis fascia as favorable points of origin of these growths. Nélaton also speaks of such tumors arising from the round ligaments. As in my own case, and in the cases quoted by this surgeon, as well as in those given by König[3] and other German authorities, from the weight and increasing size of the tumors, when arising in this locality, these tumors are apt to press inward and hang in the abdominal cavity, and even break or wear through their peritoneal coat and get free in the abdomen.

Dr. Briddon has kindly furnished me the notes of a somewhat similar case that presented itself in his wards at the Presbyterian Hospital, which may properly be here appended.

Subperitoneal fibroma of transversalis fascia.—Eliza D——, aged twenty-seven, married, was admitted to the Presbyterian Hospital, January 17, 1882, with the history that she commenced to menstruate at twelve years of age, and has always been regular. Married four years; has had three children and no miscarriages. Last child was born November 1, 1881. Last menstruated two weeks ago.

About nine months ago patient first noticed a swelling in the right inguinal region, attended with some pain. Swelling continued slowly, attended with little pain during pregnancy. Since delivery pain has become more severe and the swelling has increased more rapidly.

On examination a very hard oval tumor, 9 × 5 inches, was found in the right inguinal region, with its long diameter parallel with Poupart's ligament.

By conjoined manipulation it was at first thought to be connected with the ovary, but subsequent examinations, after it had become larger and more fixed in its attach-

[1] Presented at a meeting of the Practitioners' Society, held November 4, 1887.

[1] One week later the tubes were removed, and eighteen days from the operation the patient was walking about.—(November 18, 1887).

[2] Page 58. [3] Lehrbuch der Chirurgie, vol. i., page 155.

ments, proved it to be probably not connected with the pelvic organs.

May 4th.—Operation by Dr. C. K. Briddon. Ether; full Lister precautions; incision made the whole length of tumor in its long diameter, and the tumor easily pulled away from its attachments, except at the lower and deeper portions, which had become of late very firmly bound down to the surrounding parts. Considerable difficulty was experienced with its deepest attachments, and great care was of necessity used at that part, as it was in close connection with the peritoneum. A portion of the caput coli, about two inches square, was exposed. Considerable hemorrhage, but easily controlled. The tumor weighed two and a half pounds, and was found to have originated in the transversalis fascia.

A large drainage-tube was inserted in the whole length of the wound, and the jagged cavity left was brought together by deep silver sutures, with intermediate ones of silk, bringing the edges into close apposition.

The patient recovered well from the ether and made a good recovery without complications, except a slight and transitory cystitis. Owing to the depth and torn nature of the large cavity left, there was considerable discharge. At first the lips of the wound united by first intention throughout. The dressings were of necessity changed almost daily, and the Lister dressing was discarded about two weeks after the operation. Discharged cured. Microscopically the tumor was found to be a fibro-myxoma.

OSTEOCLASIS FOR THE CORRECTION OF DEFORMITIES.

By DILLON BROWN, M.D.,

ATTENDING PHYSICIAN TO THE OUT-DOOR DEPARTMENT OF BELLEVUE HOSPITAL; CLINICAL ASSISTANT VANDERBILT CLINIC.

Osteoclasis, like nearly every modern surgical procedure, is referred to in the earliest medical writings. The osteoclasts of Hippocrates, Apelles, Archimedes, Paul of Ægina, Celsius, Galenus, and the more modern ones of Louvrier, Bosch, Oesterlen, Blasius, Rizzoli, Bruns, Volkmann, Esmarch, Collin, Robin, Taylor, Cabot, are given in various works. The history of this operation can be presented very concisely by figuring the instrument and its various modifications.

It is easy to understand why the operation never gained popular favor before the introduction of ether and chloroform, and before the many mechanical objections to the instrument were overcome; but since the discovery of chloroform and the introduction of the simpler apparatus of Rizzoli and of Robin, the operation has become popular in France and Italy. It is hard to explain the slow progress it has made in this country toward general adoption, except by the lack of familiarity with it. The advantages of a simple fracture over a compound one are many, and surely, on this account alone, osteoclasis is entitled to a fair and extended trial. In cases where it is applicable there have been no deaths following osteoclasis, and there have been many following osteotomy. Nusbaum, of Munich, gives 242 osteotomies with 10 deaths, and 204 osteoclases without a single death. Poore collected 1,510 cases of osteotomy with 20 deaths, suppuration was reported in 109 cases, and some necrosis in 17 cases. Osteoclasis, in proper cases, is just as effective as osteotomy, and avoids the dangers from pyæmia, secondary hemorrhage, and other accidents which may follow a serious cutting operation.

Osteoclasis is useful for the correction of: 1. Rachitic deformities of the extremities. 2. Deformities following badly united fractures. 3. Articular deformities resulting from bony anchylosis. 4. Deformities following old dislocations. 5. Certain obstinate forms of club-foot.

For bow legs, manual osteoclasis can be practised in only a limited number of cases. The bones must be very soft to yield to such force, and it is in just this class of cases in which mechanical appliances are to be preferred to the harsher methods. In correcting genu valgum this manual force is known as Delore's method, or *redressement brusque*. The patient being fully under the influence of an anæsthetic, the affected limb is placed in external rotation, so that the outer side of the thigh and the external malleolus rest firmly upon the table. The surgeon applies sudden and slightly increasing force to the apex formed by the deformity until cracking sounds are heard, the knee is forced outward, and the limb can be put straight. Tillaux operates in an opposite way. The internal condyle rests upon the edge of the table, assistants steady the knee and thigh, while the surgeon grasps the leg just above the malleoli, using it as a lever with the internal condyle as the fulcrum. Sudden jerks are applied to the leg until it can be straightened. The operation requires from five to thirty minutes, and is not suitable for children after the age of twelve years. The limb is immediately put up in a stiff bandage and an ice-bag applied to the knee. The leg must be kept quiet for from three to six months, and the patient must only be allowed to walk with crutches for another year. This operation has been done over two hundred times by Delore, and many times by Tillaux and others; but there have been reported only two deaths, one by Delore from scarlet fever, and one by Tillaux from pyæmia. However, the operation is anything but a thoroughly safe one. The lesions produced by it are all of a serious nature, and the remote results of the operation are a weak and lax joint, which requires rest for a long time, and the frequent use of retentive apparatus to prevent relapses.

The autopsy on Delore's case showed the ligaments intact, but a separation of the epiphyses of the tibia and the femur, and a detachment of the periosteum from the lower portion of the femur. This observation was confirmed by the experiments of Saurel, Barbarin, and Barbier on the cadavers of infants. One or more of the epiphyses were separated in twelve cases, and the external lateral ligament was ruptured in three cases. In adults the reverse is found, and the least damage resulting will be a loose joint. Before the epiphyses will separate the ligaments will tear, and one or more condyles will break. Santi, in experiments on the cadavers of adults, found a rupture of the external lateral ligament nine times, and a fracture into the joint once, while there was a separation of the condyle in only two cases. As a result of this operation we find many cases of arthritis with effusion, not a few cases of suppurative periostitis, and necrosis from stripping off of the periosteum from the lower end of the femur, dislocation and lateral motion from rupture of the external lateral ligament, and ultimately a weak and lax joint, and the risk of a short leg from the interference with the nutrition of the bone by the separation of the epiphysis. It is a rough and unsurgical procedure, and is certain to be supplanted by the better and more precise methods of instrumental osteoclasis or of osteotomy.

Instrumental osteoclasis.—Without doubt a certain, and possibly a large, proportion of rachitic deformities of the extremities recover without either mechanical or surgical interference. In no case should constitutional treatment be neglected—good hygienic surroundings, proper food, and cod-liver oil. The hypophosphites are good, theoretically. On this account I would not apply the clumsy mechanical supports in very young children unless the deformity was very much exaggerated, but depend upon general treatment and frequent daily attempts at correction with the hands. The splints do harm, not only by altering the shape of the soft pelvis, but by interfering with the action of the already weakened muscles. If the deformity increased in spite of this, I would then apply some mechanical support.

As soon as the bones become eburnated, operative interference is necessary to correct the deformity, and it seems to me that osteoclasis is much preferable to osteotomy. It is just as effective, besides meeting the same

indications in a safer and simpler manner. It has been practically demonstrated that the great but temporary pressure brought to bear upon the soft tissues by the osteoclast does no harm, and it has been repeatedly shown, in experiments on the cadaver, that you have complete control over the point of fracture. In about thirty fractures which I made with the osteoclast upon the cadavers of children, including the tibia and fibula, the femur and the humerus, the fracture was, without exception, opposite the pressure pad of the instrument; it was practically transverse, and in only one case was there any comminution.

For bow-legs I prefer Rizzoli's osteoclast as modified by Dr. A. T. Cabot, of Boston, to whom credit is due for its introduction in this country. He obtains his counter-pressure by means of hooks instead of rings, so that the leg can be more easily removed from the instrument if it should become impacted. The instrument consists of a steel bar, and through the centre of it is fitted a heavy screw, one end of which is furnished with a handle and the other with a strong, well-padded plate. It is completed by two steel hooks, having at their upper portion a slot into which the large bar slides. Dr. Poore has had three threads cut upon the screw, thereby increasing the rapidity with which the force can be applied.

The method of operating is as follows: The patient is put under the influence of an anæsthetic. The leg is put in the hooks, which are so adjusted upon the straight bar that one comes just below the upper, and the other just above the lower, epiphysis of the tibia. The well-padded steel plate should be on the outer aspect of the leg and directly over the point of desired fracture. After the instrument is adjusted, the pressure-pad is driven down rapidly by turning the screw until the bone gives way. In bow-legs you get two distinct cracks, one due to fracture of the fibula and the other due to fracture of the tibia, and you must be certain that both bones are broken before removing the instrument. The deformity must be slightly over-corrected, and the leg held in that position by applying a stiff bandage from the toes to the upper part of the thigh. The after-treatment is that of any simple fracture of the leg. The operation is seldom followed by pain or any constitutional disturbance. It is well to remove the stiff bandage at the end of six weeks, but keep some light splint to the legs for a month or two longer.

The only accident to avoid is a separation of the epiphysis, and this can always be prevented by a proper adjustment of the instrument. Two cases of non-union have been reported, but this complication is certainly as great after osteotomy.

The correction of lateral curves and of moderate anterior curves is very simple. In marked anterior curves, the objections urged are the danger of applying so much force over the crest of the tibia, or, if the bone is broken laterally, the great amount of manipulation of the bone and injury to the soft parts required to bring the leg into good position. This difficulty is easily overcome by a tenotomy of the tendo Achillis.

Sharp curves, so near the joint that Rizzoli's instrument cannot be used without the danger of separating the epiphysis, should be corrected by some modification of Robin's osteoclast or by an osteotomy.

The report of my eight cases of osteoclasis for bow-legs can be given in a few words. The patients were all about four years of age. The curves of the tibia represented every variety—lateral, antero-lateral, and anterior. There was increased lateral mobility of the knee-joint in every case. No accident followed the operation, and the result, both immediate and ultimate, was excellent. There has been no return of the deformity, although the patients were allowed to run around in six weeks after the operation without any mechanical support. Five of these cases were operated upon conjointly by Dr. E. R. Chadbourne and myself, at the New York Foundling Asylum.

The treatment of knock-knee by splints is applicable only while the bones are yet soft. Even then it is a clumsy, tedious, and painful process, and in my own experience the results have been far from satisfactory.

Osteoclasis for the correction of genu valgum has been attempted so seldom in this country that but little is known of its merits. In 1879, Collin devised an apparatus for this purpose, and demonstrated that it always caused a separation between the epiphysis and diaphysis of the lower end of the femur—in other words, it was a better and more precise method of applying Delore's treatment by *redressement brusque*. It is a dangerous and unsurgical method, and ought never to gain general favor.

In 1882, Robin presented an osteoclast for the correction of the deformity of knock-knee by fracturing the lower end of the femur just above the epiphysis. A large number of successful cases have been reported in France and Italy. At the Copenhagen meeting of the International Medical Congress in 1884, Robin stated that nearly one hundred cases of genu valgum had been successfully treated by this instrument. It gives perfect control over the desired point of fracture, and is without the dangers of a grave cutting operation. It seems to me that it is destined to supplant osteotomy in this class of cases, *i.e.*, genu valgum due to bone deformities; thus excluding the paralytic and some other varieties.

The instrument is very simple, and its construction and method of action is easily understood. The femur is held firmly and securely by an iron case, which encircles the anterior aspect of the thigh from a point a short distance above the condyles of the femur to the upper part of the thigh. This is fastened to a heavy piece of plank by two collars, which can be adjusted to fit any sized thigh. To the lower collar is fastened a lever which passes down parallel to the leg. A strong leather strap passes around the lever, and is so adjusted that it surrounds the thigh just above the condyles. Thus we obtain a lever by means of which we can apply with precision a great force. When applying the force with this osteoclast, the limb should be rotated outward, so that the condyles will protect the nerves and vessels from injury. After correction of the deformity, the stiff bandage should be applied from the toes to the upper part of the thigh. This should be removed in from six to eight weeks, and careful passive motion begun.

Ferrari, in 1887, presented a screw osteoclast for the treatment of knock-knee, which is much superior to the lever instrument of Robin. It is very simple, and its application is easily understood from the figure.

The deformities that follow badly united fractures require at times surgical treatment, and when occurring in the long bones osteoclasis offers a simple, safe and efficient means for their correction. In cases of vicious union, the bones may unite at an angle, or one of the fragments may be rotated, and as a result of efforts to bring the neighboring joint in the same plane as the corresponding one on the opposite side, there will be pain, deformity, and a limp. I recently saw a patient with single genu valgum, due to a fracture at the middle of the femur, which united with the lower fragment rotated outward. As a consequence of this, the whole weight was thrown upon the outer condyle to enable him to bring his knee in the proper plane for walking. It has been proposed to compensate for the short leg due to overlapping of the fragments by making an oblique fracture of the opposite leg. This seems rather barbarous, but I can imagine cases in which it might be useful. In incomplete or green stick fracture, if the bones are not straightened strange deformities may ensue.

The deformities following bony anchylosis of the joints can be treated in various ways, and it is in only a small proportion of the cases that osteoclasis is to be preferred to osteotomy and other means of correction. The dangers following either *redressement brusque* or instrumental osteoclasis are many, and more or less severe, according to the joint involved. Besides the danger of lighting up

the old disease, the operation may result in a purulent arthritis, a hydrarthrosis, a dislocation, a fracture, or a rupture of important nerves or vessels. Louvrier reports twenty-six cases of flexed knee treated in this manner, and, besides encountering many mishaps, he had two deaths and a case of gangrene of the leg following rupture of the popliteal artery. The results after osteotomy, or resection, in this class of cases are so satisfactory and the dangers so few, that osteoclasis has a very limited field here. It is only when the bony union is easily broken up and it is not the result of tubercular disease, that osteoclasis should be considered. Of course, I do not consider here the stiff joint due to muscular spasm of chronic arthritis, hysteria, or sprains, nor to fibrous adhesions in or around the joint following injuries or rheumatism.

The dangers following osteoclasis in the treatment of the bony anchylosis sometimes resulting from old dislocations are severe enough to make great violence unjustifiable, and warn the surgeon to be cautious in its use. There is not only the danger of separation of the epiphysis, or of fracture near the joint, leaving the limb in a worse condition than before; but large vessels have become adherent to the capsule or the periosteum of a displaced bone, and fatal hemorrhage has resulted from their rupture in attempts to reduce the dislocation. In some cases the muscles have become contracted, and it is necessary to divide their tendons before attempts are made to break up the anchylosis.

For the correction of obstinate cases of club foot by *brisement forcé* Dr. T. G. Morton, of Philadelphia, Pa., has devised an apparatus which seems to have done good work. Dr. E. H. Bradford, of Boston, Mass., presented an instrument which seems to be an improvement, and is certainly more precise. He reported fifteen cases, and concluded that the operation should be done in only extreme cases, and in cases where a speedy result is desirable. He thinks, however, that the method is safe, saves time and trouble, and gives perfect results. I assisted him on a case three years ago, and the result was excellent. The patient was a boy about twelve years of age, with a very obstinate double congenital talipes equinovarus. Tenotomy had been repeatedly tried in vain, and the question of treatment rested between *brisement forcé* and cuneiform osteotomy. The former was done with the most satisfactory result.

Mollière reports in the *Lyon Méd.*, 1885, No. 4, p. 125, a case of obstinate club-foot treated by osteoclasis with a Robin instrument. The patient was twenty-one years of age and the result was good.

In conclusion I wish to state clearly that I do not recommend operative measures in rachitic deformities of the extremities until the bones have become eburnated, except in that class of dispensary patients in which the surgeon must correct the deformity rapidly or have no chance to treat the patient.

The principles which guide me in the treatment of these cases are:

1. In children under two years of age, in which the deformity is not exaggerated, the expectant plan, possibly with frequent daily attempts at correction with the hands.

2. In older children, in which the bones are yet soft, some form of mechanical support.

3. As soon as the bones become eburnated, osteoclasis or osteotomy.

4. Osteoclasis is to be preferred in all cases of deformity near the middle of long bones, in a large proportion of cases of knock-knee and other deformities near the joints, and only rarely in cases of bony anchylosis and club foot.

For Bites of Insects.—(1) Salicylic acid, 1 part; elastic collodion, 19 parts. (2) Corrosive sublimate, 1 part; elastic collodion, 1,000 parts. On applying either of these solutions, the pain, it is stated, is allayed at once, and it is only in the rarest cases that the neighboring parts become swollen.

Clinical Department.

A CASE OF ANTIPYRIN-POISONING.

Dr. J. S. Whitehouse, of Santiago de Cuba, writes: "A few days ago I gave a dose of seven and a half grains of antipyrin in about one drachm of syrup to a young girl, with the following bad results: About two minutes after taking it severe gastric pains came on, which augmented to such a pitch as to become unbearable. She arose in great distress, bending forward and crying out with pain, and threw herself on the floor writhing like a serpent. These symptoms were of three or four minutes' duration, when an intense eruption of urticaria came over the whole surface of the body, adding greatly to her sufferings from the intense itching, which caused her to tear her flesh with her nails. Having only warm water at hand, a large quantity was given to produce vomiting, which was aided by titillating the fauces with the finger. The symptoms became so severe that she became unconscious, and I feared death from heart-failure. Immediately one-sixtieth grain of atropine was injected, which in a few minutes caused all the symptoms to disappear, and she has had no return of them."

SOME NOTES ON ANTIFEBRIN.

Dr. F. T. Simpson, of Hartford, Conn., sends us the following: "Antifebrin is a derivative of coal-tar through the acetate of aniline, whence its chemical name, acetanilid. It is a white crystalline powder, odorless, tasteless, save a slight sensation of heat imparted to the tongue, sparingly soluble in water, readily in alcohol and ether, unirritating and unobjectionable as a powder, which is generally the best mode of administration. It enters the system rapidly from the stomach, and probably the most of it is decomposed into aniline and other products; but Drs. Cahn and Hepp, who first employed it in disease, claim to have recovered it in its own form from the urine.

"Physiological action.—In a series of experiments upon myself with it, noting pulse, temperature, and general condition before and after taking it, I obtained the following results:

"First day.—Four grains at 11 A.M. In one hour the temperature was found to be $\frac{4}{10}$ of a degree lower, and continued so about five hours. No change in pulse or general condition.

"Second day.—Eight grains at 10 A.M. At 11 A.M. temperature $\frac{6}{10}°$ lower, but by 2 P.M. back to normal. Pulse between 70–80, and no recognizable change in character or frequency.

"Third day.—At 10 A.M. temperature was 98.4°; pulse, 84. Sixteen grains of antifebrin were taken. At 11 A.M., temperature, 97.3°; pulse, 76; 12 A.M., temperature, 97.2°; pulse, 76; 3 P.M., temperature, 97.7°; pulse, 70–80; 5 P.M., temperature, 97.9°; pulse, 70–80. Here the depression of temperature lasted over seven hours, but I do not know the exact time of its return to the normal. No other changes of condition than those mentioned were noted, save a faint charcoal-taste in the mouth.

"On the fourth day sixteen grains were taken at 10 A.M., and sixteen more at 11 A.M., making thirty-two grains in an hour. Pulse continued between 70–80, and good. Temperature went down only $\frac{1}{10}$ of a degree, or less than the day before, and began to rise again by 2 P.M. Now, there was evident some tendency to perspiration. The pupils were contracted, and did not respond to light. The mucous membrane of lips and tongue was markedly blue, and there was some drowsiness, easily thrown off. The appetite, digestion, and general bodily functions were undisturbed, and the usual tasks performed.

"On the fifth day the sixteen-grain dose was repeated four times, at intervals of three hours, making sixty-four grains in about thirteen hours. The temperature was

only depressed $\frac{6}{10}$ of a degree after the first dose, and then remained at normal. The other symptoms were noted as the day before, but were not increased. The urine, which had been measured each day and found to be about the normal amount, was much darker in color. There was, however, no irritation of the urinary organs, no disturbance of digestion or appetite, no interference with sleep, sensation, or locomotion. After waiting a few days, that a possible toleration of the drug might pass away, a final trial of the cumulative effect of large doses was made, to get more positive symptoms. Sixteen grains were taken, at intervals of about two and a half hours, up to seven doses, making one hundred and twelve grains in a day. The temperature declined $\frac{3}{10}$ of a degree after the first two doses, returned after the fourth dose, and stayed at same elevation. Pulse varied between 70–80 all day. There was the same slight flushing of the skin and perspiration, the contraction and immobility of the pupils, the blueness of the mucous membranes, some drowsiness, occasional momentary pain in one of the extremities. On the other hand, three 'square meals' were taken, all professional duties fulfilled, and no one remarked any change in appearance or condition.

"As to the toxicity of antifebrin upon the healthy system, experiments with animals by Messrs. Cahn and Hepp show it to be comparatively slight. A seventeen-pound dog was given sixty grains at once, which, in comparison by *weight* with a man, would be over four hundred grains to an individual of one hundred and thirty pounds. The dog became languid, and finally dropped into a deep sleep, but was all right the next day. A thirteen-pound dog received forty-five grains for seven days, or four hundred and fifty grains to one hundred and thirty pounds. At the end of that time he died, with vomiting, spasm, and collapse. Even of aniline, the toxic component of antifebrin, some eighty grains are necessary to kill an average-sized dog. Drs. Cahn and Hepp calculate that two hundred grains, taken several days, are required to produce fatal effects in a healthy man.

"The following cases from my note-book illustrate the action of antifebrin in disease:

"Case I.—J. D——, aged sixteen years. Typhoid fever with unusually high range of temperature. On the morning of the eighth day the thermometer registered 105½°. Forty-five grains of antipyrine in fifteen-grain doses, every two hours, reduced the temperature to 103½° at night.

"On the ninth day, at 9 A.M., temperature, 104½°. Antifebrin given, two and a half grains, repeated every two hours for three doses. Evening temperature, 102°.

"Tenth day. Morning temperature, 104°. Antifebrin administered in same way. Evening temperature, 100½°. From the tenth to the twenty-fourth day antifebrin given in four-grain doses once or twice a day in the daytime. As a result, while all the morning temperatures averaged above 104°, all the evening temperatures averaged 102½°, thus inverting the usual typhoid-fever curve. No other remedy but carbolic acid and tincture of iodine, in half-drop doses, was used, but large quantities of milk were taken. Convalescence was established on the twenty-sixth day of the disease.

"Case II.—Mrs. S——. Acute phthisis. Afternoon temperature, 104°. Stomach very sensitive; rejecting both quinine and antipyrine.

"August 14th.—Four grains antifebrin given per rectum at noon. Evening temperature, 100°.

"August 15th.—Two and a half grains taken by stomach and retained. Evening temperature, 100½°. From this time on, for six weeks, antifebrin taken daily per stomach in two- to four-grain doses, the temperature never exceeding 101½° when taken, and the patient never complaining of fever.

"Case III.—Continued fever lasting a week.

"October 1st, 9 A.M., temperature, 104$\frac{2}{10}$°. Ten grains of antifebrin immediately given. At 10 A.M., temperature, 102⅗°; at 12 M., 100⅘°; at 5 P.M., 102½°. The next morning the temperature had returned to 104°, at which point it persisted, except as antifebrin was given. At the end of a week the fever left, and the patient recovered.

"Case IV.—Mrs. H——. Subacute rheumatism. Four-grain doses of antifebrin t.i.d. brought speedy and lasting relief.

"Case V.—J. P——. Violent neuralgia every two months, with premonitory symptoms. Antifebrin in four-grain doses, used at the beginning, warded off the attack, or during the paroxysm, abated the severity of the pain, though it was inferior to morphine in this respect.

"To present other cases would be simply a repetition of the foregoing. I have given antifebrin to more than twenty patients, who have taken an aggregate of above three hundred doses, and I have never known it to fail in accomplishing more or less completely the object for which it was given; nor have I known of its administration being followed by a single bad symptom among the several hundred cases reported in which it has been used; only two or three failures in reducing temperature have been heard from, and only five or six where unfavorable symptoms followed. The New York *Medical Journal* recently reported a case where, after sixty grains had been administered in twenty-four hours, collapse set in. But the physicians differed as to the cause of the collapse, and the patient recovered. The amount here given was twice the amount limited by Drs. Cahn and Hepp for twenty-four hours, and is four times the amount I ever found necessary. If a ten-grain dose failed to act, I should try another remedy, on the ground of idiosyncrasy. Antifebrin, however, has caused no fatal results even when administered recklessly—sixty to ninety grains daily for quite a period, as has been done in Germany.

"So far as is known, antifebrin is not an antiperiodic. Whether it equals the salicylates in rheumatism remains to be proved. Its greatest sphere of usefulness is to be found, I believe, in lowering the temperature and allaying the pain and restlessness of fever. Among the many antipyretics, the foremost in the general estimation are probably quinine, the salicylates, antipyrine, and antifebrin. Antifebrin has the following advantages over the others:

"1. Easy administration, being almost tasteless and retained by the most delicate stomach, while quinine, antipyrine, and the salicylates are difficult to give.

"2. Size of dose, being only one-fourth the amount of any of the others.

"3. Cheapness. One ounce antifebrin costs twenty-six cents; one ounce antipyrine, one dollar and thirty-five cents; one ounce quinine, fifty cents. In view of the size of dose, antifebrin costs only one-eighth as much as quinine, one-twentieth as much as antipyrine, one-half as much as salicyl. sod.

"4. Pleasant effect on system. Far superior to quinine and the salicylates in not causing tinnitus, dizziness, deafness, amaurosis, and general discomfort; better than antipyrine in not depressing the heart, and in increasing secretion of urine.

"5. Specific effect on temperature. Both antipyrine and antifebrin are found to be more efficient than the others in reducing fever, and I think the general testimony is that antifebrin is more prompt, decided, and lasting in action than antipyrine. Certainly that is my experience.

"6. Safety. As has been shown, twenty-five times the average medicinal dose (four grains) of antifebrin in fever can be taken without producing fatal or even serious symptoms. Twenty-five times the average antipyretic dose of quinine, the salicylates, or antipyrine would be inevitably disastrous. They all have had their victims, antifebrin none. In view of its singular efficacy and comparative harmlessness, antifebrin seems destined to take high rank among our leading therapeutic agents."

Progress of Medical Science.

Sweating Fever.—The Paris correspondent of the *Medical Press* says that, at the last meeting of the Académie de Médecine, Dr. Brouardel gave an account of the miliary sweat which ravaged certain villages in the central departments of France. The epidemic commenced on March 16th last, during an epidemic of measles. The different symptoms divided the affection into three periods, the first of which was ushered in by sweating fever, general malaise, oppression, palpitations, and even delirium, the tongue loaded, constipation, and frequent epistaxis. The second period was signalized by the miliary eruption, and commenced on the fourth day. It was accompanied by great itching, and appeared on the face, neck, and upper extremities, and ultimately over the rest of the body. In this stage the symptoms of the first period abate, fever lessens, headache disappears, and the general state of the patient is improved. The stools are black, like tar, and fetid, and hemorrhage from the nose, lungs, or intestines are often witnessed. The third period is characterized by desquamation and convalescence, and often the legs swell. Such is the course of the affection when it is of a moderate type. There are, however, two other kinds, one of which is rapidly fatal, and the other extremely benign. When the malady terminates by death the symptoms are greatly exaggerated, and seldom the third period is attained. Fever runs high, sweating is profuse, and delirium of a typhoid type precedes the coma. A great number of individuals were attacked in the recent epidemic, but the fatal cases were not many. The victims were generally adults, children escaping as a rule. In conclusion, Dr. Brouardel said he had to confess that he was not able to find out the cause of the malady.

Pathology and Treatment of Gastric Disease.—Some years ago some hope was engendered by the announcement, in a rather enthusiastic way, that in all cases of carcinoma of the stomach the juice removed from that organ by means of a tethered sponge was devoid of hydrochloric acid, while the succus similarly removed from the stomachs of patients suffering from other diseases than carcinoma contained hydrochloric acid in recognizable quantity (*The Lancet*). This discovery, had it been one, would have proved an incalculable boon to clinicians, but observations made since the announcement have shown, we believe satisfactorily, that cases of carcinoma of the stomach are not always marked by the absence of hydrochloric acid in the juice, and, on the other hand, that cases of gastric disease which to all appearances are not carcinomatous yet possess the negative quality of being found wanting in hydrochloric acid. Beno Lewy has studied cases in which great atrophy of the mucous membrane of the stomach was attended with suppression of the secretion of hydrochloric acid. M. Grundzach has examined the contents of the stomachs of several hundreds of individuals who did not present any signs of carcinoma of this organ. In five of the cases examined, the hydric chloride was invariably absent. Now, although all the five patients were dyspeptics, yet their ages (about thirty) and the absence of any other symptoms, with the very long duration of the dyspepsia, would seem sufficient to negative carcinoma. In none of them was there any interference with the mechanical functions of the stomach, for this again emptied itself in the usual space of time required by healthy organs. The integrity of the motor mechanism of the stomach in these cases seems to show that it is the aliment, and not the gastric juice, which sets the contractility of the walls of the stomach in action; though it is quite possible for a very acid juice to excite undue manifestations of contraction with too rapid emptying of the stomach, which may be followed by characteristic diarrhœa. The question of the presence of dilatation of the stomach has not always received the consideration it merits. Of course we refer to the idiopathic dilatation, supposing it to exist, and not to that which is secondary to obstructive disease of the pylorus. Germain Sée believes that dilatation may be due to degeneration of the muscle of the stomach-walls, to atony of the organs associated with general asthenia, and to a special muscular atony which, after having alternated with phenomena of exaggerated excitability, in neurastheniacs, finishes by becoming predominant and persistent. In cases of simple muscular atony, which may be due to congenital feebleness, as Mathieu suggests, the stomach, incapable of resistance, is passively distended under the influence of the pressure, if not the weight, of the aliment. The importance of dieting such an alleged case is only too apparent, and, whether the pathology be correct or not, we can bear personal testimony to the value of suppressing such articles of diet as green vegetables, salads, green fruits, and potatoes, except in the smallest quantities and especially prepared. The number of meals may be increased, while the amount taken each time should be very small. Mathieu demurs to the use of adulterated wine, and thinks beer may be drunk, but only with the meals. For the relief of painful sensations M. Sée recommends the employment of hot drinks—weak tea in the morning and light "grog" in the evening. In order to regulate the bowels in such cases, he advises the taking of a powder composed of magnesia, cream of tartar, and precipitated sulphur, mixed in equal proportions. To increase the general tone of the patient tepid and cold douches are advised, preferably of the shower-bath description, and lasting from twenty-five to thirty seconds, repeated every other day. It has been somewhat aptly said that gastrectasis is in some fashion a kind of asystole of the stomach, and that, as we require digitalis for the heart, so some medicament of similar action on the stomach is needed. Nux vomica is employed, but ipecacuanha is more successful according to others, and may be administered in syrup of orange; it does not avail, however, if the muscular fibres are degenerated as well as atonied. Chloroform water and hydrochlorate of cocaine, as well as warm drinks, may be employed to relieve the gastralgia.

The Use of the Curette and Intra-uterine Douche after Labor at Term.—Dr. J. S. Knox, of Chicago (*Journal of the American Medical Association*, November 12, 1887), inveighs against the too indiscriminate use of intra uterine measures after labor. He does not hesitate to acknowledge that many, possibly a majority, of the obstetric teachers of to-day are advocates of intra-uterine douches, some of them advising them as a prophylactic after all labors. This, however, does not affect the conclusion that they are not harmless. There is a vast difference between the conscientious care, exact methods, and skilled operations of continental maternity obstetricians and the practice of our average accoucheur. If only one of the teachers before mentioned has found such douches occasionally harmful, then are they dangerous—yes, at times murderous—in the hands of the careless many. The most enthusiastic advocates of the intra-uterine douche insist that it must be administered with the most scrupulous care. The external disinfection of the patient; the thorough disinfection of the operator; the aseptic injector passing through a thoroughly aseptic vagina; the exact temperature and force of the injection; the entire exclusion of atmospheric air from the uterine cavity; the free drainage—in fact, all the details of the operation—not one of them must be omitted. Leave out the simplest of them and the whole method is vitiated. The arch loses its strength by the removal of a single stone. How absurd even to expect this of the average practitioner or average obstetric nurse. How vicious, unless positively indicated and antiseptically practised, to deliberately ac-

cept the risk of infecting the uterine cavity. Since the use of the curette necessitates the subsequent use of the douche, the risks of the latter apply to it. In addition are the necessary admission of air into the womb; the creation of further wounds; the provocation of hemorrhage; the shock of operation, and the possible perforation of the uterine wall. In concluding his paper, the author formulates the following rules: 1. Where there is positive evidence that there is putridity or septic infection of the uterine cavity, the douche is imperatively demanded. 2. Where the douche does not succeed in abolishing the fetor or septic symptoms, the curette should be cautiously and thoroughly used. 3. Where the womb has been thoroughly irrigated and made aseptic, the douche should be discontinued. 4. Where there is septic fever, with doubt as to its uterine origin, vaginal antiseptic douches should be first attempted: only on their failure should intra-uterine douches be resorted to. 5. In purely localized inflammatory affections, with no evidence of sepsis, the intra-uterine douche is absolutely contra-indicated. 6. The intra-uterine douche should never be used simply to lower temperature. And as a corollary to the above should be added: 7. It should be considered a criminal offence to administer an intra-uterine douche without proper antiseptic precautions, or to intrust its administration to an unskilled assistant.

The Treatment of Facial Neuralgia by Antipyrine.—One by one the non-inflammatory painful affections are wheeling into line as amenable to treatment by antipyrine. Germain Sée, in speaking of this subject, says: "To complete the series of painful affections of the head which have yielded to antipyrine, I must mention facial neuralgia. I have notes of seven cases of tic douloureux, all of a very grave kind, two of which were completely cured. One resisted antipyrine absolutely, while four have experienced marked amelioration and appear to be in the way to recovery. These patients had been suffering from tic douloureux from twelve to eighteen years. During this long and frightful period of suffering, these patients had never been able, without pain, to open their mouths, to speak, to chew their food, to swallow hot or cold liquids, to expose themselves to a current of air, or to enjoy the least respite, even under the influence of morphia or salicylate of soda. These four patients are enabled now, after two months of treatment, to enjoy that freedom from pain which they had not before known for years, and to live like the other members of the family. The treatment has consisted in the daily use of 75 grains of antipyrine (15 grains every four hours, till the entire quantity was taken). I have also relied very much on the subcutaneous injections of antipyrine—8 grains dissolved in the same weight of water, and the whole injected for one dose—but as these injections have sometimes been painful, I have lately modified my formula, as follows: I now dissolve my 8 grains of antipyrine in 22 grains of water, to which, in order to enhance the effect, I sometimes add $\frac{1}{6}$ grain of cocaine. These injections act with surprising rapidity and energy. I now rely on these hypodermic injections in all inveterate cases, and during the painful paroxysms combine the hypodermic treatment with the internal administration of 75 grains a day. The results in this most grave and most intractable of painful disorders have been unprecedentedly gratifying and surprising."

Woman's Lesser Brain-weight not a Sign of Mental Inferiority.—Dr. Parkyn, writing to the *British Medical Journal* on the mental differences of men and women, says that there is no doubt room for further investigation on this subject, but all the evidence we have goes to prove most distinctly that the difference in weight between the male and female brain is simply resultant of or coincident with a corresponding difference in the weight of the male and female body. Dr. R. Boyd examined the brain of 2,036 sane persons of both sexes in the Marylebone Infirmary. He found in new-born infants that the weights were: male, 11.65 oz.; female, 10 oz. After birth the averages gradually rose in proportion to the age, but in those examined between the age of four and seven years the weights were found to be almost equal, namely: male, 40.2 oz.; female, 40.1 oz. At from thirty to forty years of age, or the prime of life, the weights were: male, 48.2 oz.; female, 43.09 oz. The intimate anatomical and physiological connection of the cerebro-spinal and sympathetic nerves with the brain would lead us to expect that they would bear a direct proportion to it, and since the nerves necessarily bear a direct proportion to the amount of tissue supplied, there must manifestly be a similar relation between the brain and the body as a whole. Since the weight of the body of woman is less than that of man, we should accordingly expect that her brain would weigh less. This theoretical conclusion is fully borne out by observation. Clendinning and others found that, in a series of 81 males, the average proportion between the weight of the brain and that of the body at twenty and upward was as 1 to 36.5; and in a series of 82 females, as 1 to 36.46. Allowing for errors of experiment, we may therefore say that the proportions are exactly the same. This conclusion is strikingly supported by the fact previously mentioned, namely, that at the age of four to seven years the weight of the female brain is almost exactly the same as that of the male. Very many persons must have noticed that at this age boys and girls differ little, if at all, in height, and experiment has further shown that they then differ as little in weight. In the present state of our knowledge it cannot be inferred that a less heavy brain is a sign of mental inferiority in the female, but is rather the state best fitted for the natural use of the bodies, the parts concerned being properly proportional. Dr. Parkyn is also inclined to believe that any deviation from this normal proportion, either above or below, is not, *cæteris paribus*, advantageous to the individual as a thoroughly healthy organism.

Inoculation against Typhoid Fever.—Inoculation against typhoid fever is the latest sanitary possibility. Brieger has discovered that typhoid bacilli secrete a ptomaic poison which he has called "typhotoxine," the injection of which into animals seems to have caused lesions very similar to those caused by typhoid fever in man. As a result of researches these conclusions appear: 1. The symptoms and alterations observed in animals in which cultures of typhoid bacilli had been injected are due to the toxic substances secreted by these bacilli. 2. The noxious germs which secrete the typhotoxine are reproduced in the intestinal canal. From these the ptomaine is taken up by the circulation and carried to all the organs liable to be affected by this poison. 3. It is most probable that the same takes place in abdominal typhoid fever of man. 4. A first infection insures immunity against injurious effects of a later infection, even of large quantities of the toxic substance. 5. Further experiments and careful clinical investigations are necessary in order to establish a scientific support of the theory of immunity from injections of sterilized cultures containing not more than a determined quantity of typhotoxine. 6. In case this theory be an ascertained fact, the reproduction of the same immunity in man would be justified by commencing with very minute doses of typhotoxine, which would be gradually increased according to the results obtained.—*The Sanitary News.*

A Sign of Constitutional Weakness.—In a recent brochure, Dr. E. Duponchel calls attention to the existence of a depressed apex-beat as a valuable sign indicative of constitutional weakness. He calls attention to the sign especially as an aid to those who are called upon to examine recruits for the army.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, December 3, 1887.

HEART DISEASE OF VALVULAR AND OF ARTERIAL ORIGIN.

M. HENRI HUCHARD, whose studies in cardiac pathology have been long faithfully pursued, presents an interesting picture of two forms of derangement of the heart. Under the terms "valvular cardiopathies," and "arterial cardiopathies," he shows how differently the action of the heart is disturbed by valvular cicatrices and arterial scleroses. He shows, also, the peculiarities of development and the treatment indicated in the two affections. It is well known that the endocardium and valves act very differently to morbid influences from the inner lining and middle coats of the arteries. The one is attacked in early life, the other, late; the one is injured by rheumatic, gouty, and infectious poisons, the other by syphilis, alcohol, tobacco, over-strain, and the degenerative changes of age.

The history of a cardiac valvular disorder as given by Huchard is divided into four stages:

First comes the early stage, when the heart is not at all affected by its valvular cicatrix. No symptoms are shown or felt, the pulse is regular, and arterial tension normal. Drugs given now are useless, or actually harmful. It is the stage of *eusystole*.

Then the work of the heart becoming a little harder by reason of valvular imperfection, the muscle hypertrophies, arterial tension is raised. It is the stage of compensatory hypertrophy or *hypersystole*. In this period also digitalis is not only useless, but harmful. Then the cardiac muscle begins to soften, the heart dilates, the arterial tension falls, œdema, congestion, dyspnœa appear. This is the period of *hyposystole*, and now digitalis is indicated. Finally the myocardium becomes gradually weaker, undergoes fatty degeneration, and does not respond to digitalis. The condition is one called by Gubler *asystolie cardioplégique*, and by Huchard, *amyocardie*. In this stage little avails in treatment; digitalis is contraindicated, and other excitants must be used, especially caffeine. In valvular lesions an important danger, according to Huchard, is weakness of arterial tension, which has often to be combated by proper agents.

In arterial cardiopathy the patient shows some signs of aging, and is often of the arthritic temperament. He suffers from an arterio-sclerosis which may be puerperal, or may affect especially the vessels of some particular viscus, such as the kidney, liver, or brain. In any case the cardiac muscle is affected, says Huchard, indirectly, even if the vessels themselves of the heart are not affected. Arterio-sclerosis, in other words, impairs the work of the heart-muscle indirectly by affecting the elasticity and calibre of the circulatory system. The three great causes given for this trouble are: 1, Toxic influence of alcohol, tobacco, and lead; 2, The diatheses, rheumatic, gouty, and syphilitic; 3, Excesses, physical and moral.

The symptoms of arterial cardiopathy may come on insidiously, in which case the peripheral arteries only are affected; or it may come on suddenly with attacks of dyspnœa, palpitations, active pulmonary congestions, and anginal attacks. In these cases the sclerosis has invaded the muscular supply of the heart to some extent. The frequent access of heart-symptoms at the menopause is attributed to an "arterio-sclerosis de la menopause," and not, as is usually done, to the hyperæsthetic nervous state of this period. This arterial cardiopathy, while it develops insidiously, often shows itself finally with great suddenness, in the form of dyspnœa, palpitations, angina, etc.; or, if the cerebral vessels are specially attacked, in hemorrhages; if the abdominal viscera, in severe disturbances of those organs, such as congestions, dropsies, uræmia, diabetes, etc.

There is then a group of cardiac affections "which have the heart for their seat and the arteries for their origin," and it is necessary to treat the arteries, not the heart. While in valvular cardiopathies arterial tension is raised only during certain periods of the disease, in arterial cardiopathy this increased tension is present from the beginning. The drugs indicated are, therefore, nitroglycerine, nitrate of amyl, and the arterial depressants. Early in the disease also, iodide of potassium is a helpful remedy for the sclerosis. In order properly to deal with the arterio-sclerosis it is necessary to recognize it early, and Huchard insists upon the great value of the "diastolic echo of the aorta," *retentissement diastolique de l'aorte*. It is like the stroke of a hammer simply duplicated. It is heard most plainly in the second and third intercostal spaces, near the right edge of the sternum. The sign, to be of value, must be found to be permanent. Together with this, one may note a hardness in the radial pulse, and the patient may have attacks of pallor of the face, local anæmias, syncopes, and asphyxias of the extremities, attacks of polyuria, palpitations, vertigo, etc.

It will be seen that Huchard is describing much such a state as has been studied by Mahomed, Johnson, and the late Dr. McBride, a state to which they gave the name of the pre-albuminuric stage of Bright's disease. Huchard takes a wider view of the matter, and finds a condition which is antecedent not only to renal, but to cardiac, cerebral, hepatic, and other visceral disturbances. In conclusion, he claims that the condition of arterio-sclerosis as portrayed is different from those senile changes which harden the arteries without necessarily being accompanied with an arterial spasm, or a great degree of sclerosis.

THE TREATMENT OF WHOOPING COUGH.

THERE are many diseases in the history of which our therapeutic resources have not kept pace with our pathological discoveries. Of this class pertussis is a notable

illustration. It is generally regarded as a systemic disease, with characteristic local manifestations. The discovery of its germ has been announced. Conclusive proof by inoculation and the reproduction of the disease have not, to our knowledge, been definitely determined. As is the case with so many of the general diseases, there seems to be an abortive form of the malady, in which the duration is not much over two weeks. This fact must be borne in mind in attaching value to any plan of treatment. Such abortive cases are apt to run in epidemics, and the experience of anyone may at a given time be entirely confined to this class of cases.

The treatment by antispasmodics became long ago well established, and is still the one followed by many physicians at the present day. A so-called "specific" for pertussis was found to contain only bromide of potassium and fluid extract of hyoscyamus. With other physicians the treatment is mainly directed to the general bronchitic symptoms. Advocates of these two therapeutic procedures hardly claim to be able to abort the disease, or, to any great extent, to lessen its entire duration. They content themselves with lessening the severity of the paroxysms.

Still a third resource is the use of the tincture of belladonna, which has come to be regarded by many as a specific. In order to be of service its administration must be pushed boldly, even in very young children, up to the full physiological effect. This remedy does seem to have a decided effect, not only in diminishing the severity of the paroxysms, but also of actually shortening the duration of the disease.

A new method of treatment, proposed some two years ago, or rather, perhaps, brought again into prominence, is that of insufflating antiseptic powders into the nares and naso-pharynx. The advocates of this plan regard pertussis as a parasitic or microbic disease. The habitat of the morbific agent is in the anatomical sites just mentioned. The paroxysms are due to reflex disturbance transmitted therefrom. When this insufflation was first practised one of the German authorities used simply inert powders, to see if there was any mere physical effect. No modification of the malady was produced. A further trial with various medicinal agents, in powdered form, gave decidedly beneficial results.

In a recent number of the *British Medical Journal* Dr. George Holloway contributes a very readable article on his experience with insufflation. He does not think we have found the germ of the disease. He has his patients confined to one room. Into each nostril and the naso-pharynx is insufflated, every three hours in the daytime, and once during the night, two or three grains of boracic acid. At the end of ten days the child is allowed to go out, if the weather is favorable.

Dr. Holloway's article recites the issue in twenty-one cases. Four were under six months of age, five from six months to a year, seven between one and and two years, four between two and three, and two at six and eight years respectively. In one case the disease was completely cured at the end of three weeks. At the time of the child's coming under observation it was having twenty-eight paroxysms daily. The use of the boracic acid was at once begun. On the second day there were only twelve paroxysms, and thereafter a gradual daily reduction to six on the seventh day. One case was complicated with spasmodic croup. A calomel purge gave no relief, but boracic acid afforded immediate benefit. The possible supervention of broncho-pneumonia need not intermit the insufflations. Without going into details in all of Dr. Holloway's cases, we may say that they seemed to be of ordinary severity, and that the duration in every case was much less than with the old plans of treatment. Guerder, of Paris, and Mayer, we believe of Hamburg, have reported similarly favorable results.

Finally, one other method deserves notice. It is that of cleaning a room, removing all woollen fabrics therefrom, and then thoroughly fumigating it with sulphur dioxide gas. After twenty-four hours the room is thrown open, aired, and, as soon as possible, the sick child is confined therein. It is claimed that thereby is the severity of the disease distinctly lessened, and in many cases convalescence seems to directly follow. It need hardly be said that this device inclines to the germ-theory of the disease.

THE LATEST HYPNOTIC.

It has been a great year for antipyretics and hypnotics. One after another they have been heralded to the public—each one claiming superiority to its predecessor. The wonderful development of various departments of organic chemistry has materially assisted therapeutics. This has been especially true with hypnotics. Paraldehyde, urethan, and others have been welcome additions to our list of remedies, and now a new claimant demands recognition. It is known to the chemist as di-methyl-ethyl-carbinol and is formed by the action of sulphuric acid on tri-methyl-ethylene. It was discovered by Wurtz, and is a member of the group of tertiary alcohols. The physician contents himself with the simple name—amylene hydrate.

Von Mehring has given the most complete account of its action that has yet appeared. In a recent number of the *Therapeutische Monatschrift* he describes the new remedy as a clear, colorless liquid, slightly lighter than water, soluble in eight parts thereof, and miscible in all proportions with alcohol. It has a distinct, penetrating odor, like many of the volatile oils.

Von Mehring has been watching its effects upon men and animals for the past two years. He can speak, therefore, with considerable positiveness as to his conclusions. He has found an average dose to be about four grammes. In regard to power—it is midway between chloral and paraldehyde. It scarcely affects the pulse and respiration, but confines itself entirely (with the above dosage) to quieting the cerebrum. No nausea, vomiting, headache, or, in fact, bodily disturbance of any kind follows its administration. Like chloral, when insomnia is associated with or is directly due to pain, it is unreliable. Its taste is much less disagreeable than that of paraldehyde.

In poisonous doses, respiration is slowed, reflex action disappears, the medulla is gradually depressed, and cardiac failure ensues. An important fact is mentioned by Von Mehring—namely, that extensive cardiac lesions do not seem to be unfavorably affected by the remedy.

The general therapy is that of sleeplessness of nervousness—of all grades, even up to delirium tremens

and the insomnia of the various febrile diseases. In only four out of sixty cases did it seem of no avail. Its palatability and freedom from danger are two valuable features. Therein is it preferable to either chloral or paraldehyde. It can be given in enema, as well as by the mouth.

THE LOCAL TREATMENT OF PULMONARY DISEASE.

The modern methods of treating locally chronic bronchitis, chronic interstitial pneumonia, and phthisis, are three, viz., by sprays, inhalations, and the pneumatic method. Dr. B. F. Westbrook has given an interesting summary of his views and experiences with these methods (*Medical News*, July 30, 1887).

In chronic bronchitis all three forms are employed. The passages are first cleansed with a spray containing an alkaline solution: ℞. Acid. carbol. cryst., ℥lxx.; sodii bibor., ʒiij.; sodii phosph., ʒij.: glycer., ℥j.; aquæ, ℥vj. A fifty per cent. solution of carbolic acid in glycerine is then added to this cleansing mixture until the point of tolerance of the patient is reached. Sometimes, instead of the carbolic acid, a spray of fluid extract of hyoscyamus, ʒss. to ℥j., is used. If there is copious secretion, tannin and glycerine or iron salts are employed.

The pneumatic method is claimed to produce very good results in chronic bronchitis. The negative pressure used is very slight, being only from two-tenths to five-tenths of an inch. The cabinet is contraindicated in asthma and emphysema. The Evans inhaler is becoming popular among physicians in this city, and offices are frequently decorated with it. The appearance of the apparatus is attractive, the idea ingenious, and the method of its use agreeable to the patient. It is a modification, according to Dr. Westbrook, of the idea of Sales-Girou, and depends upon the principle that when a coarse spray is forcibly thrown against a surface it will be broken up into minute particles and form a fine nebula which will float in the atmosphere several minutes before being precipitated or evaporated. The grosser part of the spray remains in the globe, and falls through a tube back into a bottle, while the more finely nebulized portion is carried off through the tube of exit, from which it is inhaled by the patient. The mouth-piece consists of a hard-rubber tube with an opening on one side.

The patient is instructed to make deep and slow inspirations, with the idea of securing, as far as possible, voluntary expansion of the chest. The solutions employed have been about the same as those used in the spray and the pneumatic cabinet, viz., carbolic acid, hyoscyamus, and pine-needle extract.

The disadvantages or limitations of the apparatus depend on the fact that there is no preliminary cleansing. This can be accomplished, however, by first using the strong spray from the Sass apparatus.

The elaborate and expensive machinery involved in the use of high-pressure sprays, nebular inhalation, and pneumatic differentiation are not within the reach of all, though we believe that physicians could wisely spend more money on therapeutic appliances than they at present do. To such as cannot get these things, however, a strong hand-spray for cleansing, and a Burney (Geo.) respirator for wearing over the mouth and nose, can be recommended.

In the local treatment of chronic interstitial pneumonia with bronchiectasis, by which term is meant, we presume, the fibroid phthisis of some writers, Dr. Westbrook says three objects are to be accomplished. First, the healing of the bronchial catarrh; second, disinfection of the dilated bronchi; and, third, the restoration of the breathing capacity of such portions of the lung as are not hopelessly degenerated.

The first two objects are best accomplished by the use of the coarse spray or the Evans inhaler, the coarse spray being the more serviceable.

The third object is to be accomplished through the pneumatic cabinet.

In the treatment of the initial stage of phthisis the pneumatic cabinet is spoken of as highly serviceable; but, we may ask, what agent cannot be spoken of in this way as long as incipient phthisis is so amenable to palliative treatment? The defect of the cabinet in connection with the introduction of sprays, etc., is that while these may be deeply inhaled, they are not so completely exhaled, the increased amount of air drawn into the lungs being residual rather than tidal. It seems that the ideal cabinet should have a negative pressure during inspiration, a positive during expiration. Sprays and inhalations in phthisis appear not to have been so extensively used, because of the satisfactory results obtained with the cabinet. For cleansing purposes or the treatment of intercurrent bronchitis these measures are resorted to successfully.

MADE INSANE BY THE FAITH-CURE.

We have already called attention to the pernicious and demoralizing effects of the faith-cures and mind-healing upon the mental condition of the victims of this humbug. A pain may be made to disappear, but the will is weakened and the character enervated by the process. On the whole, a faith-cure college is a far greater social evil than a liquor-saloon, for its effects are more insidious and far-reaching. It is not a matter for surprise to learn that a woman is recently reported to have been made insane by the faith-cure. The incident occurred in Chicago, and the faith-healer is likely to be indicted for practising medicine without a license.

SHALL THE DOCTOR MARRY RICHES?

This important question is being discussed by some of our contemporaries with such earnestness as to suggest that the matter is becoming a personal issue with some representatives of medical journalism. Dr. N. Senn (will not our distinguished *confrère* fill out his first name and put those ever-recurrent "Ns" in the minority?) has written that it is a fashion in Europe among medical men to marry rich wives, and he thinks that marrying wealth brings social obligations antagonistic to science. In this he is right; yet, on the other hand, for grinding, uncompromising antagonism to science there is nothing that goes far ahead of poverty. The scientific buds nipped by the frost of matrimonial multiple-millionairism are few compared with those whose bloom chill penury and a large family repress. The worldly wisest of

Americans, Benjamin Franklin, broke off his first engagement because the parents would not mortgage their house to give the daughter a modest dower. And though the prudent Franklin subsequently married a poor girl, he did so with some misgivings, and left the impression that a dower was the proper thing for the wise and good to expect. Looking at the matter in the same cold and worldly light, we should express the opinion that the doctor ought to marry neither poverty nor riches; but elect to love some charming woman whose resources would lessen the worry incident to a large family and a small practice. However, it is useless to advise in matters where sentiment is bound to rule.

FATAL RESULT OF CIGARETTE-SMOKING.

THE number of boys, in the cities especially, who begin to smoke cigarettes at the age of ten or eleven years is enormous. In most cases the habit is not indulged in excessively, and no serious harm is done, though growing boys cannot take nicotine without suffering from it to some extent. In not a few cases chronic disorders of the nervous system occur. The report comes from Philadelphia of a boy, eleven years of age, who died from tobacco-narcosis. He had been smoking half a dozen or more cigarettes daily for ten months.

There could be no more salutary law than one forbidding the sale of cigarettes to minors.

SOME NEWLY DISCOVERED VIRTUES OF PHOSPHORIC ACID.

PHOSPHORIC acid is not a remedy that has hitherto enjoyed much of a reputation, its employment having been chiefly that of a tonic, giving place even in this application to the other mineral acids. But if some recent therapeutical experiments can be accepted, this drug possesses virtues which will serve to place it in the front rank of curative agents.

In the *Gazzetta Medica Italiana* for October 29, 1887, Dr. Antonio Grossich reports a number of cases in which most remarkable results followed the external use of phosphoric acid. He was first led to employ it from a consideration of the results obtained by Kolischer in the treatment of local tuberculosis by interstitial injections of a solution of calcium phosphate. He tried local applications of the same solution in the treatment of ulcers of the leg, and found it to give satisfactory results. But, as there were no tubercles in these cases, the action of the remedy ought to be explained otherwise than by a calcification of the tubercles, and the author concluded that the phosphoric acid must be the active agent. Acting upon this belief, he began to treat all his cases of obstinate ulcer of the leg by local applications of a ten per cent. solution of strong phosphoric acid in distilled water, the compresses being renewed three or four times a day. The results obtained were so satisfactory that he was encouraged to try the same substance in various tubercular affections.

In the case of two young girls, suffering from multiple ulcers of the neck following tubercular adenitis, the application of a solution of phosphoric acid of the above-mentioned strength brought about a cure in five weeks. The injection of the solution, in another case, into an enlarged gland of the neck effected a reduction of the swelling and induration within twenty-four hours. Suppuration of the gland followed later, but was limited to a very small part of it.

Perhaps the most striking results were obtained in a case of caries of the wrist. The disease had lasted a year, and the hand was greatly swollen from the carpus to the metacarpo-phalangeal articulations, and there were two sinuses, one on the dorsum and the other in the palm, communicating with each other. Pressure on the hand caused the exit of blood mingled with pus and caseous matter. Exploration with the probe showed a large extent of carious bone and a general undermining of the soft tissues. The hand would ordinarily have been condemned by anyone to amputation. Trial was first made of interstitial injections by means of a hypodermic syringe, but little improvement followed; and then recourse was had to daily irrigation, through the sinuses, with the phosphoric acid solution, compresses wet with the same being applied in the interval. Some benefit was observed from this treatment, and it then occurred to the author to immerse the hand in the solution. Two such baths were given daily, each of two hours' duration. At the end of seven weeks the sinuses were closed, the swelling was reduced more than one-half, and there was free motion at both the carpal and metacarpo phalangeal articulations.

A tubercular abscess of the walls of the chest, treated by free incision and stuffing of the cavity with lint wet with the phosphoric acid solution, was completely and permanently cured in less than four weeks. Finally, in a case of chronic eczema marginale, in a girl twenty-two years of age, applications of the same solution had, at the time of writing, two weeks later, caused such marked improvement that the author felt confident of effecting a perfect cure within a short time.

Dr. Grossich reported a number of other cases than those to which we have referred, in which he obtained equally good results. He is naturally somewhat enthusiastic in his praise of this remedy in the treatment of ocal tubercular processes, and he believes that phosphoric acid has a future before it which would never before have been imagined. Lentin, it may be stated, some time ago recommended the use of a ten to twelve per cent. solution of phosphoric acid in the treatment of caries, believing that this process was due to a deficient amount of the acid in the osseous tissue. The cases in which he tried these applications were benefited somewhat, but he obtained no such brilliant results as those reported by Grossich.

A HOMŒOPATH IN THE INTERNATIONAL MEDICAL CONGRESS.—At the recent meeting of the Ninth International Medical Congress, held in Washington, Dr. George S. Norton, of New York City, a professor in a *Homœopathic* medical college, author of a work upon the *Homœopathic* therapeutics of the eye, surgeon to *three Homœopathic* hospitals, and a member of *five Homœopathic* medical societies, upon invitation of the President of the Section in Ophthalmology became a member of the Congress, and read a paper upon "The Importance of Correcting Small Errors in Astigmatism."—*The Clintonian.*

News of the Week.

The New York Academy of Medicine received on Monday a donation from Mrs. John Jacob Astor of $1,000. The gift was made through Dr. Fordyce Barker, and is to be used for the library and building funds.

The Hypodermic-syringe Thief, of which mention has been made in a previous issue, has been apprehended and committed to the lunatic asylum. He persisted in "borrowing" syringes of physicians and not returning them until a few days ago, when a physician of this city, acquainted with his methods through The Record, caused his arrest. The poor culprit proves to be a physician from Chicago, who, some months since, became a victim of the cocaine habit and used the means alluded to to satisfy his craze for a narcotic, by not only securing a syringe, but by having it loaded for him either with Magendie's solution or cocaine. His plea was that his wife was dangerously sick in the neighborhood, that the physician had broken his syringe and desired a syringeful of the drug for the emergency.

Interneships in the New Methodist Hospital in Brooklyn.—The first pavilion of this hospital, founded by Mr. George I. Seney, will be opened with appropriate ceremonies on December 15th next. It will afford accommodations for about seventy-five beds, and will be thoroughly equipped for the work of a general hospital. Two "interne" appointments are to be made at once, and the Medical Board solicit applications for these positions from recent graduates. It is desired that one, at least, of these positions shall be filled by one who has already had hospital experience. Applications should be made either to Dr. L. S. Pilcher, 145 Gates Avenue, Brooklyn; or to Dr. A. E. M. Purdy, 304 Madison Avenue, New York City.

Excision of the Larynx.—Gardner reports an excision of the larynx for epithelioma, occurring in a man sixty years of age. A rectangular lead tube of the full diameter of the trachea was first inserted between the cricoid cartilage and the first ring of the larynx. Through this the anæsthetic was given, and it prevented the passage of blood down the trachea. The entire larynx was removed and the patient supplied with an artificial one, by means of which he could talk so as to be understood. Four months after the operation the patient was very comfortable and well nourished, but the disease had recurred.—*New York Medical Journal.*

Professional Secrets.—The Twelfth Congress of Italian physicians, which recently met at Pavia, voted by a considerable majority, but not unanimously, in favor of abolishing the obligatory disclosure by the physician of professional secrets. It still remains for the law to be changed in accordance with this vote. Perhaps the opinions of Italian doctors have some weight with the law-makers. They do not have very much in this country.

The Danger of Being Funny.—The humorous *feuilletoniste* of the *Union Médicale* not long ago argued that no apparatus was necessary for carrying out the Bergeon method of treating consumption. It was only necessary to make the patient eat beans. He now states that Professor Ewald afterward presented the idea, in all seriousness, at a meeting of the *Gesellschaft für innere Medicin*, of Berlin.

Bequests to Charity.—By the will of the late Moses Wildes, of Boston, the sum of $150,000 is to be divided equally among a number of local charities, chiefly medical. Cambridge Hospital gets $20,000 in addition.

"Physiology as She is Taught."—The attempt to teach physiology in the schools of lower grade reaches the acme of absurdity in certain physiological primers now being published. The dominant idea in these is that human beings are made up in such a peculiar way that alcohol and tobacco easily, seriously, and constantly poison them. Here are some review questions for tender infants: "What does alcohol do to those who drink it? What do people sometimes think of home-made wines? How can alcohol be there when none has been put into it? What does alcohol make the person who takes it want? Are you sure you will not become a drunkard if you drink wine?"

The New York Cancer Hospital, Eighth Avenue, 105th and 106th Streets, will be opened with appropriate exercises on Tuesday, December 6th, at three o'clock P.M. Short addresses will be made by the President, John E. Parsons, Esq., and by Dr. Fordyce Barker and Dr. W. H. Draper. The medical profession is invited to be present. The building will be open for inspection from three to six o'clock of the same day, and patients will be received on Wednesday, December 7th. Nearest elevated railway station at 104th Street, exit from Central Park at 100th Street.

Tight Lacing and Bright's Disease.—Dr. W. B. Neftel, of New York, writes: "In The Medical Record of November 26th I read the following: 'Tight Lacing and Bright's Disease.—Dr. Neftel claims that tight lacing predisposes to renal disease, . . . but renal disease is more common in males than in females.' What I said reads as follows: 'My experiments on animals have demonstrated that a prolonged compression of the chest and abdomen invariably produces general anæmia, and venous congestion of the liver and other abdominal and pelvic viscera.'"

Dr. Thomas L. Janeway, of New Brunswick, N. J., died recently at Eureka Springs, Kan. He was a graduate of the College of Physicians, and was in his forty-third year.

Burial without Coffins.—The movement to secure burial reform, now being undertaken in this city, is a much needed one and deserves encouragement. We have often pointed out that a vast deal of the habitual invective indulged in by cremationists against earth-burial would have no force if the burial methods were improved. The object of the New York Association for the Promotion of Burial Reform is the reduction in the expense of funerals, and the doing away with coffins, caskets, and sealed boxes of all kinds. In place of these, wicker wrappings and papier-maché boxes are to be used.

A New Hospital for Brooklyn.—The Seney Hospital is soon to be opened in Brooklyn. The corner-stone was laid five years ago, but delays have occurred, owing to financial difficulties. Mr. Seney expended

$417,000 for the institution, and money from the Methodist Church has subsequently been raised sufficient to make the amount already applied about half a million. Only one wing of the hospital is completed as yet. The capacity of the entire hospital will be 400 beds. It is claimed that Brooklyn greatly needs this hospital, as it has only one hospital bed to every 1,000 inhabitants, while London has 7 to each 1,000. New York has, counting all its smaller institutions, 40 hospitals, with over 5,000 beds, or one hospital bed to every 260 inhabitants.

Dr. Stanley Smith, of Reading, Pa., died on November 25th, aged forty-three years. He was a graduate of the '65 Class of Amherst, studied medicine with Professor B. Howard Rand, of Philadelphia, completing his studies at the Leipsic University, Germany. He was elected lecturer in Physical Diagnosis in Jefferson Medical College, a position he held for two years.

Dr. Theodore R. Varick, one of the best-known physicians and surgeons in New Jersey, died at his home, Jersey City, on November 23d, aged sixty-two years. He was born in Poughkeepsie, but went to Jersey City forty years ago, and has ever since lived there. He was appointed surgeon-general of New Jersey by Governor Randolph, and held that position until last year, when he resigned his position. He had been one of the board of managers of the State Asylum at Morris Plains, and at the time of his death was a member of the medical staff of the Jersey City Hospital, medical director of St. Francis' Hospital, of Jersey City, and president of the Hudson County Board of Health. He was the first one to introduce in this country Trendellenberg's method of amputating the hip-joint.

The New York Society for the Relief of Widows and Orphans of Medical Men held its annual meeting last week, and re-elected Dr. Gouverneur M. Smith president, and Dr. Hinton treasurer. This most deserving society has won a membership of 136. It has extended aid to twelve widows and five children of deceased members during the year.

Medical Latin.—Professor Esmarch is said to be leading an attack upon apothecaries' Latin, and urges the abolition of the use of Latin in prescription writing. Perhaps it is the distinguished inventor of the elastic bandage who set in circulation the following:

Patient: I suppose, doctor, you write your prescriptions in Latin, so that your patients can't read them?

Doctor: Well, yes.

Patient: And I suppose you write your bills in English, so that your patients can understand them.

The French write their prescriptions in French to a large extent, judging from the formulæ in their medical literature. The result is that their prescriptions are the most unintelligible part of their scientific literature. The tendency was never greater than now to use the terms of a universally known tongue in scientific nomenclature.

SIR MORELL MACKENZIE'S ACCOUNT OF THE CROWN PRINCE'S CASE.

After the removal of the growth last summer, and the subsequent application of electro-cautery, no recurrence of the growth took place. Some general congestion of the larynx remained, and while His Imperial Highness was in the Isle of Wight a slight thickening of the mucous membrane on the posterior surface of the arytenoid cartilages near their base was observed by Dr. Norris Wolfenden, at that time in daily attendance on the Crown Prince.

At one of my weekly visits I verified Dr. Wolfenden's report, and perceived that the thickening presented the form of a ridge, raised to the extent of about a millimetre, of yellowish color, and extending horizontally from the outer border of one cartilage to that of the other. The action of the left vocal cord, which had been noticed in Berlin to be slightly impaired, continued in the same state. It should, perhaps, be here mentioned that soon after His Imperial Highness arrived in England a marked disposition to catarrhal inflammation of the larynx and trachea, or fugitive congestion, was observed.

A rather sharp attack occurred in the Isle of Wight, and this was followed by general relaxation of the mucous membrane of both the pharynx and larynx. The congestion disappeared while the Crown Prince was in the Highlands, and during this period the thickening at the base of the arytenoid cartilages already described was absorbed. On the return of His Imperial Highness to London the condition of the larynx was on the whole satisfactory; the movement of the left vocal cord was much more free, and the voice strong though not quite clear, owing to a slight increase in the congestion having taken place on leaving Braemar. The Crown Prince's general health was excellent.

On September 9th a slight thickening was noticed on the posterior extremity of the left vocal cord, which increased for a few days, and then gradually disappeared, being on the 18th no longer visible. For a few days previous to the development of this thickening the larynx generally had again been more congested. On September 13th Dr. Evans, of Paris, extracted the Crown Prince's left lower second molar tooth, which was much decayed, the fangs showing the result of a considerable amount of periostitis.

On September 14th an oblong thickening of the mucous membrane, about five millimetres in length and three in width, was observed by Mr. Mark Hovell nearly half an inch below the middle of the left vocal cord and parallel with its free border. Mr. Hovell states that this swelling gradually increased in size, and when seen by me on September 22d it was nearly round, and measured rather more than half a centimetre in diameter. Two days later the Crown Prince took cold, and on the following day complained of a sense of fatigue, disinclination to take food, and great sleepiness in the daytime. On examining his throat the left ary-epiglottic fold was found to be œdematous. His temperature was 101° F.

In twenty-four hours the œdema had entirely disappeared, and the temperature had become normal. Although the œdema was apparently due to cold, the possibility of its being caused by limited perichondritis was discussed at the time. The acute swelling had no apparent effect on the little thickening below the left vocal cord, *which gradually became smaller, but did not entirely disappear.*

The Crown Prince continued to enjoy good health after his arrival at Baveno, and when I left Italy everything appeared satisfactory, though slight general congestion remained, as well as the thickening referred to previously.

On the evening of October 17th Mr. Mark Hovell noticed a marked increase in the congestion of the larynx, both vocal cords being of a bright-red color. During the next few days the congestion decreased, but on the 21st the hyperæmia again increased in intensity, and was more diffused. On the 27th an increase was noticed in the size of the thickened surface beneath the left vocal cord, and at the same time slight general tumefaction of the

left side of the larynx appeared. During the next few days the thickened surface slightly increased, and on the 31st the surface was seen to be irregular, and in one place there was a distinct spur or projection.

The next day superficial ulceration of the new formation was noticed, and the left vocal cord was seen to be slightly swollen along its free edge. On the 28th the voice of His Imperial Highness was quite clear, and, indeed, in the opinion of the Crown Princess, was perfectly natural; but since this date the Crown Prince has been much more hoarse. On October 30th a slight reddish projection was noticed beneath the *right* vocal cord; this remained stationary for two or three days, then disappeared, and formed again on November 5th. On November 1st a slight enlargement of the left submaxillary gland was noticed, and this subsequently increased in size.

On November 3d the new formation had further enlarged, and was now rather more than a centimetre in diameter, and raised to the extent of about four millimetres. The extension of the growth since it was first seen had always been upward. On the morning of the 4th a very slight œdema was noticed at the base of the left arytenoid cartilage, which disappeared in the evening, and was again present on the morning of the 5th.

On the following day I arrived and found the state of the larynx such as Mr. Hovell had described to me.

On the afternoon of the 8th intense œdema of the mucous membrane covering the left arytenoid cartilage was noticed, and in the evening the œdema involved the entire fold, which was tense and red. On November 9th the patient was examined by Professor Schrötter and Dr. Krause, but owing to the œdema it was impossible to obtain a complete view of the new formation at the lower part of the larynx. On November 10th the patient was again examined by the same physicians, and also by Dr. Moritz Schmidt; the œdema was already much diminished, and a good view could be obtained of the whole of the larynx.

In my opinion the œdema is due to limited perichondritis, which, in its turn, has probably been set up by the growths which have been formed from time to time in the larynx. Although the nature of the growth which has lately appeared has not been determined by microscopic examination, it presents every appearance of cancer.

The above report is published by the wish of His Imperial Highness the Crown Prince of Germany. A copy of it was sent on Monday to the *Berliner Klinische Wochenschrift and London Lancet.*

Reviews and Notices of Books.

THE PRINCIPLES AND PRACTICE OF MEDICINE. By the late CHARLES HILTON FAGGE, M.D., F.R.C.P., Examiner in Medicine in the University of London, etc., including a Section of Cutaneous Diseases, by P. H. PYE SMITH, M.D., F.R.C.S., Lecturer on Medicine at Guy's Hospital; Chapters of Cardiac Diseases, by SAMUEL WILKES, M.D., F.R.S., Physician to Guy's Hospital. Vol. II. Philadelphia: P. Blakiston, Son & Co. 1886.

IN this, the second volume of Fagge's valuable treatise, the diseases of the heart, of the alimentary tract, of the urinary organs, of the bones and joints, and of the blood are discussed in the same scholarly manner characterizing the chapters of the first volume.

The diseases of the skin are treated of with undue length for the purposes of a general text-book on medicine. This section of the work might with advantage have been considerably abridged, or else omitted altogether. On the whole, however, Fagge's work will constitute a lasting monument to the industry, ability, and sound judgment of the lamented author. It will certainly compare favorably with any of the standard works on the subject in the English language.

A TEXT-BOOK OF PATHOLOGICAL ANATOMY AND PATHOGENESIS. By ERNST ZIEGLER, of Tubingen. Translated by DONALD MACALISTER, M.A., M.D., St. John's College, Cambridge. Three Parts, complete in one volume. New York: William Wood & Co. 1887.

THE English version of Ziegler's admirable treatise on pathology has already been reviewed in these columns. The present issue differs from the English publication only in combining three parts in one volume. It makes a rather bulky book, but as there is a complete index reference to any subject is quickly accomplished. The translation is made from the first and second German editions, although, owing to the great and just popularity of this text book, a fifth German edition has already become necessary.

A HANDBOOK OF GENERAL AND OPERATIVE GYNECOLOGY. By DR. A. HEGAR, Professor of Obstetrics and Gynecology, and Director of the Gynecological Clinic, at the University of Freiburg; and DR. R. KALTENBACH, Professor of Obstetrics and Gynecology, and Director of the Gynecological Clinic, at the University of Giessen. Edited by EGBERT H. GRANDIN, M.D., Obstetric Surgeon to the New York Maternity Hospital; Instructor in Gynecology at the New York Polyclinic; Fellow of the Obstetrical Society, etc. In two volumes, with 248 wood-engravings. New York: William Wood & Co. 1887.

THESE two volumes are the sixth and seventh of the Cyclopædia of Obstetrics and Gynecology which is being issued as Wood's Library of Standard Authors for 1887. The first volume, which is chiefly from the pen of Hegar, contains chapters on gynecological examinations, minor therapeutic manipulations and elementary operations, and operations on the ovaries. The last chapter is, with the exception of the chapter on what is unpleasantly designated castration, the work of Kaltenbach. The last-named is the author of the greater part of the second volume, which treats of operations on the uterus, broad and round ligaments, and vagina; operations for urinary fistulæ; operations on the vulva and perineum; prolapse operations and operations on the tubes. The two last-named chapters are by Hegar, the balance of the volume being by Kaltenbach. This handsome book is well known among gynecologists as a standard work, and the subscribers to the series are to be congratulated upon their possession of it.

DISEASES OF THE FEMALE URETHRA AND BLADDER. By F. WINCKEL, M.D., Professor of Obstetrics and Gynecology at the Royal University, Munich.

DISEASES OF THE VAGINA. By A. BREISKY, M.D., Professor of Obstetrics and Gynecology at the Royal University, Vienna. With 99 wood-engravings. Edited by EGBERT H. GRANDIN, M.D., Obstetric Surgeon to the New York Maternity Hospital; Instructor in Gynecology at the New York Polyclinic; Fellow of the Obstetrical Society, etc. New York: William Wood & Co. 1887.

THIS is Volume X. of the Cyclopædia of Obstetrics and Gynecology, constituting Wood's series of Standard Authors for 1887. The first half of the volume is a translation of Winckel's treatise on "Diseases of the Female Urethra and Bladder." It comprises sixteen chapters, treating comprehensively of all the deformities, congenital and acquired, and diseases to which the urethra and bladder in woman may be liable. Breisky's excellent work deals with equal detail with the deformities and diseases of the bladder in woman. These are both very practical monographs, and serve to maintain the high reputation for excellence which the preceding volumes have already earned for this valuabe work.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 4, 1887.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. CHARLES L. DANA read a paper entitled

CHOREA, TIC CONVULSIF, AND THE HYSTERICAL SPASMODIC DISORDERS OF CHILDHOOD.

The reader stated that there was a very considerable confusion in the views ordinarily held as to the true chorea of Sydenham and allied forms of spasmodic neuroses. He held that, leaving out epilepsy, these could be classified into chronic chorea of Sydenham, tic convulsif or spasmodic tic, of French writers, and hysterical spasmodic disorders.

Chorea of Sydenham was a very distinct disorder ; its pathological anatomy was fairly well established, and it presented clinical features that marked it almost as a specific disease. *Tic convulsif* was often mistaken for chronic chorea. Some forms of it were wrongly termed electric chorea. This name was given to a fatal disorder occurring chiefly in Italy, and described by Dubini and others. It was a name given also to a peculiar endemic chorea by Bergeon. The use of the name in peculiar forms of supposed chronic chorea, really of spasmodic tic, was unjustifiable. Spasmodic tic was a chronic disorder tending to localize itself on certain groups of muscles. The choreas of the larynx and of the diaphragm were really *tics*. The disease was one involving higher centres than in chorea ; it was more nearly allied to hysteria, and was a pretty certain evidence of a neurotic or degenerate nervous system. It was sometimes associated with peculiar explosive disorders of speech, "echotalic," "coprotalic," and movements of imitation, "echokinesis."

There were co-ordinated forms which constituted the peculiar "nervous habits," such as blinking the eyes, twitching the mouth, sniffling, peculiar gestures, etc. The slight choreic movements of young children, called "habit-chorea," were more like an aborted chorea.

The speaker gave the characteristics of the peculiar chronic hysterical-spasmodic disorders observed, especially in children. These took the forms of spasmus nutans, trochaic chorea of Laycock, saltatory spasms, and perhaps paramyoclonus multiplex. The distinctive features were described, and illustrative cases were reported of oscillatory *tic*, saltatory *tic*, trochaic chorea, etc.

An analysis of the histories of one hundred and thirty cases of chorea was given, with reference to etiology, course, duration, and treatment.

In the chronic forms of chorea and tic, the writer was strongly convinced of the value of galvanic currents applied to the head and body, in a manner described by himself several years before.

DR. KINNICUTT said that, while recognizing the grounds for, and believing in, the desirability of separating simple chorea from the spasmodic tics of children, occasionally cases were observed which rendered such a positive division as that mentioned by Dr. Dana extremely difficult. A very careful study of these exceptional cases was desirable.

Within the past several years he had seen two cases of typical *laryngeal chorea* (so called), which clinicians were at present disposed to regard as examples of spasmodic tic, associated with typical *general chorea*. The sounds made by the patients were not explosive in character (resembling cough), which obtains in spasm of the expiratory muscles, but partially articulate and jerky in nature.

In both cases repeated attempts at laryngoscopic examinations were ineffectual, chiefly from the presence of general choreic movements.

His experience, from the observation of a large number of cases of chorea, was very similar to that of Dr. Dana as to the frequency of coexisting cardiac disease.

He had personally made careful physical examinations in every case of chorea which had been seen at the clinic for nervous diseases at the College of Physicians and Surgeons, in the out-patient department of the New York Hospital, and in the wards of St. Luke's Hospital, for a number of years, and the physical signs of heart disease had been found but in a comparatively small proportion of the whole number.

DR. BEVERLEY ROBINSON asked Dr. Dana where he would class those cases in which there were seen so frequently, especially in girls, the peculiar twitchings of the shoulders.

DR. DANA replied that Weir Mitchell had described them as habit-chorea, but it had seemed to him that they were more like the cases which Charcot had described as inco-ordinate tic. Of course, the relations of these varieties drifted into each other, but he was inclined to regard them as cases of tic rather than of chorea.

DR. ROBINSON had not seen it develop into other symptoms markedly choreic in character, but it had yielded to the ordinary treatment for chorea. He had used the arsenite of soda, which had served him a better purpose than the potassa.

As to chorea laryngis, he would merely refer to the fact that it was exceedingly difficult to make an examination which would enable one to judge with regard to the condition of the larynx.

DR. A. H. SMITH mentioned one case of chorea laryngis occurring in a clergyman. The affection was not noticeable in ordinary conversation, but whenever the voice assumed its professional character a spasm of the larynx would occur every few minutes, which interrupted pronunciation entirely ; he had noticed the interruption particularly in words containing the vowel *o*. The gentleman had consulted many authorities in laryngology, both here and abroad, but had not derived any benefit.

DR. PEABODY inquired with regard to

THE DOSES OF THE CRYSTALLINE HYOSCYAMINE FOR CHILDREN

which were effective and safe.

DR. DANA had used a solution made in alcohol and water in the proportion of one grain to the ounce, and of that had given seven or eight drops at first and increased to nearly twenty drops, which meant about $\frac{1}{40}$ of a grain. He therefore began with $\frac{1}{100}$ or $\frac{1}{80}$ of a grain, and gradually increased to $\frac{1}{40}$ of a grain three times a day. The physiological effects were about the same as those of atropine.

DR. KINNICUTT'S results, obtained from different methods of treatment, very closely coincided with Dr. Dana's. He had seen a marked abatement of the choreic movements accompany the use of hyoscyamine, but with the discontinuance of the drug the disorderly movements had recurred. He had usually commenced with $\frac{1}{200}$ or $\frac{1}{150}$ of a grain, and increased to $\frac{1}{50}$ without producing any unfavorable effects. He thought that, as yet, the actually observed lesions in cases of simple chorea were not sufficiently numerous to warrant a positive statement as regards its pathology in *all* cases.

DR. SEXTON had been somewhat surprised that under the head of etiology no mention had been made of

THE PROCESS OF DENTITION.

The amount of nervous exhaustion in second dentition, from six to twelve years of age, especially with the appearance of the first permanent molars, must be extraordinary, and then it was that the children acquired such habits as winking, twitching certain muscles or groups of muscles, etc. He thought the study of these movements was incomplete without a consideration of the process of dentition. As to the treatment, he had found that aconite in minute doses was as efficacious as any

remedy he had employed; two or three drops of the tincture added to half a tumblerful of water and given in teaspoonful doses. He had not found that antispasmodics or tonics were especially serviceable.

The proper regulation of the diet and hygiene, with out-of-door life, seemed to accomplish more than medicine.

Dr. Loring said that he saw a large number of young patients, and he would remark, first, that he saw only a very small number of cases of chorea among them, and, second, that he had seen no greater number of cases of chorea in children with errors of refraction than in those without these errors, and that those who did have chorea with errors of refraction were not benefited in the least of their chorea by the use of glasses alone.

Dr. Loring also referred to the

NYSTAGMUS OF MINERS,

a peculiar convulsive movement of the eyes, acquired by lying upon the back and picking the coal above. It differed from the ordinary nystagmus sometimes seen after great fatigue.

Dr. Robinson had, on several occasions, before bringing children under the influence of arsenic or zinc, found, contrary to what Dr. Dana had stated in his paper, that the ether-spray to the spine had produced temporary benefit; at least, so marked had the benefit been that, as a measure for affording temporary relief, he thought it should not be discarded, but, on the contrary, should be regarded as a valuable adjuvant in the treatment of these cases.

Dr. Dana asked Dr. Kinnicutt if his case was not one in which the *expiratory* muscles were affected.

Dr. Kinnicutt replied that it was not a case of cough, and it did not take the form of speech, but it was a sound intermediate between the voice of an animal and that of a human being. It was impossible to examine the larynx. The boy had not only this spasm, but there was so much movement of the body that a satisfactory laryngoscopic examination could not be made.

Dr. Dana said that all the cases he had seen were apparently explosive spasms of the expiratory muscles, which resembled cough somewhat.

He excluded chorea from those cases, because chorea was an affection of those muscles which were more highly organized, supplied with the latest developed nerve-tissue. The expiratory muscles were more automatic and less liable to be affected.

Dr. Kinnicutt said it was possible to suppose that the two conditions could exist together.

Dr. Dana said, with regard to the pathological anatomy, that he had been rather dogmatic; but, as the result of eighty post-mortem examinations, the latest writers were inclined to speak with more positiveness than was done two or three years ago. He believed that it could now be said that a hyperæmic condition of the gray matter of the spinal cord was the characteristic lesion, and that it might involve the basal ganglia or cortex. He thought that in the majority of cases emboli were not present.

With regard to Dr. Smith's case, he would be inclined to regard it as one of

PROFESSIONAL NEUROSIS,

like writer's cramp. Of course, he would not say positively that it was of that character.

With regard to the influence of second dentition, it certainly was a very interesting point, and one which deserved to be studied more than it had been in connection with the cases of choreic movements.

Dr. Peabody continued the history of the case of

POISONING BY ILLUMINATING GAS,

which he reported at the last meeting. At that time the patient was doing well. Soon after she became drowsy, and then semi-comatose, in which condition she remained for nearly a week, manifesting a certain amount of contracture of the right arm and right leg, and then died.

At the autopsy, he found a very small patch of softening in the left optic thalamus, about as large as the tip of his little finger. Besides that there were the senile vascular changes, and also the senile changes belonging to the kidneys.

Dr. Kinnicutt reported a case of

TYPICAL HYSTERIA OCCURRING IN A BOY SIX YEARS OF AGE,

which he thought was not common. The symptoms were chiefly those of psychical disturbance. He said that, in his experience, hysteria in children under twelve years of age was almost as common in boys as in girls. The child had recovered entirely.

Dr. Dana had not seen hysteria in so young a child as mentioned by Dr. Kinnicutt. He referred to a case reported by Dr. Gillette, in which the patient was eighteen months old.

Dr. R. F. Weir presented a specimen of

FIBROMA OF THE ABDOMINAL WALL.

(This paper is published in full on page 703.)

URETHRO-VESICAL CALCULUS—MEDIAN LITHOTOMY.

Dr. George F. Shrady presented a phosphatic vesico-urethral calculus weighing two hundred and fifty-seven grains, removed by median lithotomy from a boy nine years of age, a patient of Dr. E. B. Ramsdell. The operation was performed without a guide, but otherwise in the usual manner, as it was impossible, on account of the firm impaction of the calculus at the neck of the bladder, to introduce a staff into that viscus.

The stone when removed was of an irregular dumb-bell shape, was two and a half inches long, and a constricted portion near its centre corresponded with that which was surrounded by the neck of the bladder. One extremity, which was larger than the other, was contained in the dilated prostatic urethra. He thought it a very unusual situation for a stone, never having seen one of such a size in that locality before. The patient recovered without a bad symptom.

Dr. Weir referred to a specimen presented to the Medical and Surgical Society by the late Dr. Alfred C. Post, in which the tongue of a calculus projected into the prostatic urethra, but not more than half as long and half as wide as the calculus presented by Dr. Shrady.

Dr. Sexton reported a case of

FACIAL PARALYSIS AND VERTIGO CAUSED BY THE IRRITATION PRODUCED BY A DEAD TOOTH.

The patient came under his observation about two weeks ago for trouble referable to the left ear, with some noise in the right ear. He had also fallen in an attack of vertigo several times while at the table eating. While crossing the Atlantic he was exposed somewhat, and when arrived in New York he had left facial paralysis. There was history of syphilis, but examination of the ear was negative, and there was nothing that pointed to a central origin.

On further examination it was found that the second upper bicuspid tooth on the left side had been filled, and it was ascertained that the dentist removed the nerve and filled the cavity about one year ago, while the tooth was sore, and that it had remained sore ever since. The tooth was removed, and in less than two weeks the facial paralysis and nearly all the symptoms of which the patient had complained had disappeared, only a certain amount of tinnitus remaining.

Two pus-sacs were found attached to the end of the fang when the tooth was extracted, and it was evident, from the subsequent history of the case, that it was one in which the cause of all the clinical phenomena was peripheral rather than central.

Dr. Weir mentioned the case of a notorious *bunco-steerer* who entered his service at the New York Hospital, having received a blow upon the side of the head sufficiently severe to rupture the drum membrane, cause bleeding from the ear, and produce facial paralysis quite marked from the beginning, and which would probably be permanent. This possibly might serve to identify the man.

The Society then went into executive session.

OUR LONDON LETTER.

(From our Special Correspondent.)

PAPERS AT THE MEDICAL AND CHIRURGICAL SOCIETY—MR. ARBUTHNOT LANE ON THE MODE OF FIXATION OF THE SCAPULA AND ITS BEARING UPON FRACTURE OF THE CORACOID PROCESS—AN ALTERNATIVE OPERATION TO EXCISION OF THE HIP-JOINT—THE DEPUTATIONS TO THE PRIVY COUNCIL FROM THE ASSOCIATIONS OF FELLOWS AND MEMBERS OF THE ROYAL COLLEGE OF SURGEONS—MR. ERNEST HART'S ADDRESS—REPLY OF THE LORD PRESIDENT OF THE COUNCIL.—THE MORTON LECTURE—THE SCARLET FEVER EPIDEMIC.

London, November 12, 1887.

Mr. Arbuthnot Lane, of Guy's Hospital, is one of the most indefatigable workers among our younger surgeons, and is constantly bringing before the societies the results of his researches—mainly on the subject of bone and joint affections. At the last meeting of the Medical and Chirurgical Society he "had the field" in an unmistakable manner. Both the papers read were by Mr. Lane, and the reading of them, with the discussions, took up the entire time of the meeting. The first paper was on the mode of fixation of the scapula and its bearing upon fracture of the coracoid process. In extreme flexion of the shoulder, he said, the scapula underwent a movement of rotation which was abruptly limited by the impact of the coracoid process upon the under surface of the clavicle. The frequent performance of this movement under the influence of strain determined in laborers the development of a coraco clavicular articulation. There was often great difficulty in breaking down adhesions which had resulted from inflammation. This difficulty arose from that of fixing the scapula. It might be firmly fixed by flexing the shoulder-joint completely, the coracoid process and clavicle being held firmly in apposition. When the scapula was thus fixed against the clavicle, the humerus could be forcibly rotated upon its own axis, and also very considerably abducted and adducted, without being accompanied in its movements by the scapula. All adhesions could thus be readily broken down. Mr. Lane then criticised the statements made by surgical writers that the coracoid process is always broken by direct violence, and showed that when the shoulder-joint was fully flexed this was practically impossible. He maintained that the published statistics as to the relative frequency of fractures of the several bones were inaccurate. He had never once seen a fracture of the coracoid in the dissecting-room, but fracture of the acromion occurred more frequently than that of any other bone in the body.

Mr. William Adams and Mr. Clement Lucas both agreed with the author in his anatomical and physiological conclusions, but Mr. Adams said that he could not accept the surgical conclusions, for it would not be possible to flex an anchylosed joint. Mr. Lucas agreed that fracture of the acromion was more common than was supposed. Mr. Howard Marsh thought the difficulties of fixing the shoulder-joint were not so great as had been inferred by the author. If, under anæsthesia, the joint were really fixed, he would advise that it should be let alone. He remarked that the acromion might be apparently detached by chronic rheumatic arthritis, to which Mr. Arbuthnot Lane rejoined that he considered injury a more frequent cause of the changes in the acromion.

A paper by Mr. Lane was then read in which he suggested an alternative operation to that of excision of the hip-joint in certain cases. In examining three hundred and twenty bodies, he had observed several instances of fracture of the femur, of which three were ununited and the rest united. In a few cases he found that a large proportion of the superjacent weight of the trunk was transmitted to the femur through a new joint which had formed between a strong, dense mass of bone on the femur (projecting upward and inward from the anterior inter-trochanteric line and the neighboring part of the femur) and the ileum, immediately beneath the anterior inferior spinous process. An attribute common to the three specimens in which this condition was present was a very considerable displacement of the head of the femur downward, which so altered the direction of its articular surface as to render it more or less useless for its original purpose. Mr. Lane referred to the unsatisfactory results of excision of the hip joint, and suggested that if the upper extremity of the femur could be displaced inward, and connected with the innominate bone so as to form a new joint similar or identical in character with that which had developed in the specimens he had observed, a very useful limb might be obtained, and one that would readily transmit the weight of the body without the assistance of any support, and permit of compensation of the shortening. Mr. Barker thought Mr. Lane's suggestion would prove a valuable one. Mr. Pick referred to the outgrowth of the buttress of bone from the fractured femur as affording a support through which the weight of the body could be transmitted. Mr. Warrington Haward defended the operation of excision, and remarked that in cases where it was successful good union and power might result in spite of great shortening. Mr. Howard Marsh also spoke in favor of excision, which was a very different operation now, he remarked, to what it formerly was.

At the Annual Meeting of Fellows and Members at the College of Surgeons, which I reported in my last letter, it was stated that the matter would be argued out before the Privy Council. The Associations of Fellows and Members, respectively, have lost no time in the matter, for yesterday afternoon a numerous and important deputation from each association attended at the Privy Council Office and had an interview with the Lord President of the Council. Mr. Timothy Holmes spoke on behal of the fellows, and Mr. Ernest Hart appeared as the champion of the members. Mr. Hart's worst enemies cannot deny that he is an effective speaker. His quiet, restrained manner and velvety tones carry conviction much more than any amount of declamation. His address was lengthy, and largely historical. He showed that the present College of Surgeons represented the united interests of the barber-surgeons and fellowship of surgeons, of which it was the lineal descendant, and could thus be traced back to the fourteenth century. He traced the analogies between it and the other city guilds, and pointing out that the freemen of the guild had always had the right of meeting and discussing the affairs of the guild and of voting, maintained that the annual meetings which had been summoned of late years by the council were merely a revival of the ancient custom, and as such deserving of special notice. Mr. Hart dwelt with some emphasis on the fact that at these recent meetings the council had "submitted" to the assembled fellows and members a detailed report of the proceedings of the college during the year, and a balance-sheet. The argument based upon a comparison of the ancient guild of surgeons with the other city guilds was somewhat spoiled by the President of the Privy Council pertinently asking whether it was not a fact that the ancient guild of

surgeons was limited to London, thus differing from the present College of Surgeons of England.

Coming down to modern times, Mr. Hart dwelt on the anomaly of twenty-four (mainly) metropolitan surgeons ruling the college. Nearly every practitioner in England and Wales was a member of it. Yet on its council there was no representative of either military or naval medicine, the sanitary service, or the poor-law medical service. It was only quite recently, and under the most extreme external pressure, that any steps had been taken by the council of the college toward the putting down of unqualified practice or removing unworthy members from its roll. It was only within the last few years that any representatives of provincial surgery had obtained a place on that board. Mr. Hart exposed in merciless terms the various subterfuges of which the council had been guilty, and quickly showed the fallacy of the various arguments which had been put forward by them as sufficient reasons for not acceding to the wishes of the fellows and members. One or two other gentlemen then briefly addressed the President of the Council, and the latter then briefly replied. He reminded the deputation that while, on the one hand, an inquiry into the past history of the college might confirm their view, it was, on the other hand, quite possible that it might sustain the opposite view. In any event, he would carefully consider the case, and the various statements submitted should have his careful attention. In reply to a question as to whether counsel would be admitted to plead before the Privy Council in support of the various legal points raised, the president replied that the matter could hardly be considered by the Privy Council from a legal point of view. The previous charter must, he said, be accepted as a legal and valid one, having remained unopposed for so many years. The sole question now under consideration was as to the granting of the supplementary charter for which application had been made by the Council of the Royal College of Surgeons.

Yesterday afternoon Sir James Paget delivered the Morton Lecture at the College of Surgeons. Of this I shall give some account in my next.

The epidemic of scarlet fever shows no signs of diminution as yet.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE EFFECTS OF ALCOHOLISM—THE INFLUENCE OF MALARIA IN PRODUCING LESIONS OF THE NERVOUS CENTRES—SYPHILIS AND DEBAUCHERY—THE DUALITY OF THE BRAIN.

PARIS, November 11, 1887.

APROPOS of the effects of alcoholism referred to in my letter which was published in THE MEDICAL RECORD of October 29th, I may relate the following conversation, which was heard at a dinner given by one of the leading members of the Paris Faculty.

One of the guests, a medical man, recalled to mind an anecdote apropos of Claude Bernard. The illustrious physiologist often reproached his friend Balard, the celebrated chemist, with the habit he had of frequently taking small glasses of brandy during his meals, under the pretence of favoring his digestion. To this Claude Bernard responded by a demonstration of the action of alcohol on the stomach. After having, he said, got dogs to ingest divers alimentary substances, he made them swallow a certain quantity of alcohol. In opening their stomachs, a few hours after, he found that these substances had undergone a notable arrest in their digestion, and that even several of them had not been at all affected by the gastric juice. Claude Bernard then addressing Balard, asked him what he concluded from the experiment. To this question Balard gravely replied: "I conclude that alcohol was not made for dogs."

After a long practice in malarious countries, Dr. Bourne, a naval surgeon, has acquired the conviction that the nosological list of paludal affections is much longer than that generally admitted. According to the theory which the author developed on the subject at a recent meeting of the Academy of Medicine, malarious infection can determine congestive and inflammatory lesions in the nervous centres. These lesions, at their onset, are amenable to the specific treatment of infection. In other cases, either that the treatment had been applied too late, or that the accidents had been too violent from the commencement, they may persist in spite of this specific treatment, and evolve independently of their infectious cause.

There is a widespread opinion among the general public that syphilis is invariably the result of debauchery, or that it is acquired only when one voluntarily exposes himself or herself to the risk of contracting that disease, and that, consequently, the prophylactic measures ordained by the authorities against syphilis would only apply to those who are not worthy of such precautions, as they ought to be able to look after themselves. In a report read before the Academy of Medicine, in the month of June last, on the best means for preventing the propagation of syphilis, Professor Fournier, the well-known syphilographer, in continuation of his investigations on the subject, repudiated such a notion as that entertained by the public, and in a second report, which he recently read before the Academy of Medicine, the author points out that in a great number of cases of syphilis, particularly in females, the disease is contracted unwittingly, or, as the author expresses it, innocently. During the last twenty-seven years that he has been practising, Dr. Fournier has been consulted in his own consulting-room by 887 women affected with syphilis. Of this number 842 cases were of sexual origin, and in 45 cases, which is already a proportion of five per cent., the disease was contracted otherwise than by sexual connection. As regards the social position of the 842 cases, the author divides the patients into three categories: 1, Women belonging to the demi-monde, 366; 2, married women, 220; 3, women whose social position was unknown, 256. In striking out from the figures 220 a certain number of the cases of married women who evidently got the disease from another source than from their husbands, there remain 164 infected by their husbands, and in 34 cases Dr. Fournier was not able to see the husbands. In conclusion, the average number of women who were infected with syphilis during conjugal intercourse would fluctuate between nineteen and twenty per cent. In concluding his report, which is published at length in the Comptes Rendus of the Academy, and which is well worthy of perusal, Dr. Fournier points out that the measures proposed by him would not only protect the dissipated portion of the public, but they would also protect honest women and their children, the innocent victims *par excellence* of this redoubtable scourge.

The question as to the duality of the brain and of the spinal marrow occupies a very important position in physiology. The greater part of medical men maintain that motion, and particularly that produced, under the influence of the will, in the members of one of the sides of the body, depends only on one-half of the encephalon and of only one side of the spinal marrow. The same is the case for the transmission and the perception of sensitive impressions, and also for vaso-motor influences exercised by the cerebro-spinal centre. As regards special sense, it is nearly the same. The *right* half of the encephalon and the *left* half of the spinal marrow alone serve, it is believed, for the *left* side of the body for voluntary motion, for vaso-motor action, for transmission, and for sensitive perceptions. The *left* half of the encephalon and the *right* half of the spinal marrow alone serve, it is asserted, for the *right* half of the body. In a paper recently read before the Academy of Sciences, Professor Brown-Séquard communicated a series of facts

tending to prove that these opinions are not correct, and that we must admit, on the contrary, that each half of the encephalon and of the spinal marrow can serve for all the functions of the two halves of these nervous centres. The following are the conclusions of the paper as formulated by the author: 1. "Anæsthesia, paralysis, and hyperthæmia, caused by an organic lesion of the nervous centres, can be transferred from one side of the body to the other under the influence of a second lesion of these centres; hence it follows that these manifestations are not necessarily the effects of the destruction of certain nervous elements possessing certain functions, and may be the results of pure dynamic actions, exercised at a distance by the irritation caused by the lesion. 2. One-half of the encephalon can serve for sensibility, for voluntary motion, and for vaso-motor actions for the two halves of the body. The same is the case for one lateral half of the spinal marrow, at least as far as concerns sensibility and vaso-motor actions."

EUROPEAN OPINIONS OF AMERICAN PHYSICIANS.

To the Editor of The Medical Record.

Sir: Noticing a quotation in a recent issue of The Record regarding the status of American physicians in Germany, it occurred to me that I might add a few items of interest to the subject by relating some recent personal experiences while abroad.

Thanks to letters of introduction from such men as Professor Jacobi, I had ample opportunity to mingle with prominent medical men in Germany and Austria, and to converse with them on all topics pertaining to American medicine. My observations are thus neither local nor superficial. I remained, also, as long as a month at a time in such localities as Carlsbad and Franzensbad. These prominent health-resorts, above all others, are frequented by physicians of all nationalities, and consequently it is very easy to form a widespread estimate of current opinions.

Prejudice against American physicians is universally encountered, mingled perhaps with a trace of jealousy. The great strides made by America and by American institutions cannot be fully appreciated by conservative Europe. It is a well-known fact that the curriculum of German universities has changed but very little, while American colleges, as business enterprises, have not lost opportunities for profiting by the mistakes of senior institutions in Europe. Europeans concede that Americans *as a nation* are very practical; that is, they "are young in old age," remaining observant and progressive throughout life. "You Americans are very practical," was a compliment often bestowed, but not to be taken in its fullest meaning.

First, let me say a few words about preliminary education. It is well known in Germany and Austria that a general collegiate education is not requisite for entrance in American medical schools. Such a thing is impossible in Europe. The idea of men matriculating in professional colleges on simple payment of fee, without even a rudimentary education, is ridiculed abroad. Thus far, as regards general education, their opinion is well founded. Starting with this idea, an idea but too true, we must admit they are naturally prejudiced against our medical education. They claim that a man devoid of most ordinary knowledge is unworthy of the title doctor, *i.e.*, wise man.

The five years' course may certainly be said to be no longer than our compulsory three years' course, when we consider the absolute number of hours devoted to actual study; besides, in our "practical" American schools we exclude such useless branches as zoology and non-medical botany. These subjects have no direct bearing upon the study of medicine, and merely waste the time and scatter the energies of the student.

European physicians appear to be ignorant of this fact, as was proved to me by numerous absurd questions asked of me. Among these was the following, which I was condemned to hear repeatedly, "Do your medical students dissect, and is such dissection actually compulsory?" Naturally, a question of this kind provokes indignation. Another question, as brilliant and complimentary as the former, was put to me by several prominent physicians, who ought to have a knowledge of what is going on in foreign countries. This question was, "How are your prescriptions written, in English or ———?" One physician was afraid to say Latin, for fear, perhaps, that an American might never have heard of the language. On one occasion I answered the question rather emphatically, whereupon my questioner remarked, as an apology, that in France prescriptions were written in French.

With a natural pride for American physicians I was often mortified to learn how few of the leading men on this side of the Atlantic are known there. There is some comfort, however, in the thought that men who are likewise distinguished in Europe are never heard of in this country.

While in Germany I formed the acquaintance of my esteemed friend Dr. Boas, one of the editors of the *Berliner Klinische Wochenschrift*. Through him I learned that men like Professor Jacobi, Professor Thomas, and other medical writers are known to almost everybody. Dr. Lewis Sayre is esteemed through his brilliant advocacy of the spinal apparatus. The most renowned American is, of course, the late Dr. J. Marion Sims, the founder of American gynecology. The Sims position and Sims speculum have been universally adopted in Europe. Dr. Thomas also has made himself famous through his work on "Diseases of Women," which is found in the library of almost every physician in Europe. Regarding the surgeons, inquiries were very frequently made of Drs. Hayes Agnew and Gross, of Philadelphia; and if the modesty of the editor of The Medical Record would permit, I would add another name, from New York. Besides these gentlemen, distinguished specialists like Dr. Herman Knapp and Dr. Lange, who have been educated in Germany and are now practising here, are, of course, well known to their colleagues. In general, I found that those men who have contributed to medical literature have gained a reputation by virtue of such contributions. Etiquette prevents me from enumerating the names of equally prominent men who are never heard of outside of America, because, as I believe, they have never taken the trouble to publish the results of their valuable experiences.

It seems very odd to an American to find European physicians, without exception, located on the second, third, and sometimes even fourth story. To occupy the ground floor being considered vulgar, patients are obliged to climb several flights of stairs to satisfy the demands of fashion. Office-hours are kept but once a day, usually from 2 to 3 P.M. This is undoubtedly very practical, because a man can devote the rest of his day to professional calls, if necessary.

The European doctor claims to be solely devoted to his profession. He looks upon the American as a mere man of business, one whose only object is to attain wealth by means of his profession. Our foreign brother's ambition is to acquire fame, to satisfy which he will sacrifice both health and wealth. More than that, he is literally at the mercy of his patients, never asking a fee nor sending out a bill for services. Thus we can readily understand why the income of noted physicians is at times very small. The maximum fee mentioned was "twenty marks," *i.e.*, less than $5. Five thousand marks yearly is considered a very good income in Germany while, as we know, it is far below our American average.

We are accused of harshness toward the poor, because our system of dispensaries is not understood. The German as well as the Austrian Government employs special district physicians for attending the needy. While

explaining the dispensary system to several physicians, it was usual for them to remark that we overdo medical charity.

In general, America appears to be as much an unknown land as it was before its discovery by Columbus. As an example of this blissful ignorance, allow me to mention the following ludicrous incident: A brilliant young *confrère* in Franzensbad said to me, "What kind of a place is your America? To my mind it pictures itself only like a wilderness. Are there many wild Indians in New York?" I jokingly answered that no one would dare to go through the streets unarmed by night or day. Noticing that he believed what was said, I, of course, attempted to enlighten him about our barbarous country. Whether he believed the truth more than the joke is doubtful.

When we compare the average young American physician with the average young European physician, we find the former much brighter and much better adapted for the practice of medicine. For, while studying medicine but three years, we study nothing *but* medicine; whereas, if we deduct the time wasted (?) by foreign studies, and then deduct the time wasted by "beer-drinking," we find that the American physician is better fitted to commence his career as a practical physician than our European *confrères*.

Nevertheless, the American physician is treated in Europe with contempt, and regarded almost as a nonentity. He is not allowed to practise without having passed a college examination *in matura*, a special examination on subjects of general culture, and, furthermore, a rigid state examination. As is seen from this, every possible obstacle is laid in our way, and hence no American physicians that I know of have settled down to practise in Germany or Austria. They acknowledge that our graduates know enough of actual medicine to apply it successfully to practice, but their theory is that a universal education, similar to the one they have received, is absolutely requisite to qualify a man to be a doctor of medicine. Though the fact disproves their theory, they take a delight in applying the old schoolmen's formula of the Middle Ages, that "if the theory does not agree with the fact, so much the worse for the fact."

It is true we may not be able to cope with them in Latin and Greek, but, all in all, I would prefer having an American attend my family in case of need than a European. Very respectfully,

LOUIS FISCHER, M.D.

40 RIVINGTON STREET, NEW YORK.

"AIDING THE BOARD OF HEALTH."

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: I hope you will find a prominent corner in THE MEDICAL RECORD which you can devote consistently to a brief reply to the communication published under the above heading in a recent issue of your journal.

The two "important impediments" mentioned by the gentleman in his communication *did* occur to the author of the paper entitled "How can the Medical Profession Aid the Board of Health?"

In explanation of the first impediment permit me to say that a condition of things which a physician recognizes by the aid of his medical knowledge, or otherwise, to be a nuisance, on account of it being "dangerous to life or detrimental to health," is a proper matter to report to the Health Department.

In reply to the second impediment I will state that a complainant is not required as a witness by the Board, since the Board depends on its own experts alone for a verification of the original complaint, and also for evidence to sustain the justice of an order made by the Board to abate a nuisance.

However, cases might occur in which the Board would desire the testimony of citizens, especially if important business interests are to be interrupted on account of the creation of a generally recognized nuisance in connection with them.

Certainly no one appreciates the inability of the busy physician to study the "Revised Statutes and Session Reports" more than the "author;" yet at the same time no one can appreciate more fully than the gentleman himself the fact that such a course is entirely unnecessary, for a medical education alone fits the physician for reporting the things of a causative nature that should be remedied by the Board of Health for the prevention of disease.

It seems to me to be proper to state that the busy physician even can, with justice to the cause he serves, give an occasional moment to gaining information of such subjects as ventilation, plumbing, etc., and of their relation to disease, especially since "an ounce of prevention" may be often quite as potent of good as "a pound of cure"—when dispensed.

If the gentleman will kindly refer his suggestions regarding "laws and ordinances," and the proposed "bulletin for the New York Academy of Medicine," to Dr. C. R. Agnew, the Chairman of the Committee of Conference with the Board of Health just appointed by the Academy of Medicine, the Commissioners of the Health Department will be pleased to do all in their power to comply with any request that the committee may make bearing on these subjects.

Very respectfully,

JOSEPH D. BRYANT, M.D.

66 WEST THIRTY-FIFTH STREET, November 21, 1887.

HONOR TO WHOM HONOR IS DUE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE RECORD for August 20, 1887, under the head of "A New Mode of Treating Burns," is a notice by you of the method of Professor Mosetig, by the use of iodoform, and the new mode of treatment is given in detail as a matter of professional interest.

Mosetig's treatment is excellent; it is undoubtedly the treatment *par excellence* for burns of the second and third degrees, even if of considerable extent (for I have not known, nor have I heard of, any evil effects from absorption, and I have used it extensively for the past five years), but there is nothing new about it, and it is not a method to which Professor Mosetig can lay any claim of originality; for in a very practical paper, under the head of "The Local Treatment of Burns," in THE RECORD for December, 19, 1882, the use of iodoform by almost precisely the same method is advocated, and a case in which such treatment was carried out is given by Dr. Robert T. Morris, then an interne in Bellevue Hospital, and he makes the same claim—that patients thus treated are soon relieved of all pain.

Yours truly,

W. H. BENNETT, M.D

188 SIXTH AVENUE, BROOKLYN.

A PECULIAR EFFECT OF TOBACCO SMOKE.—Dr. Batten reports, in the *Journal of the American Medical Association*, a curious case of idiosyncrasy in regard to tobacco smoke. A man came into his office one evening to be examined for life insurance, and, as the writer was smoking, asked him to desist, saying that otherwise he would not hold himself responsible for the consequences. He stated that the smoke first caused an intense pain over both eyes, causing him to knit his brows; then he became, as he termed it, "cranky," and would fight with his best friend. After this cranky condition lasted for a time, he became sick at the stomach, and would throw up the contents of his stomach, after which he would have to lie down. He further stated that his mother had the same idiosyncrasy with regard to tobacco smoke, and he believed he inherited it; his father was a smoker.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 20 to November 26, 1887.

SMITH, A. K., Lieutenant-Colonel and Surgeon. Assigned to duty as Attending Surgeon in New York City. S. O. 269, A. G. O., November 18, 1887.

SMITH, J. R., Lieutenant-Colonel and Surgeon. Ordered for duty as Medical Director Department of Dakota. S. O. 269, A. G. O., November 18, 1887.

HORTON, S. M., Major and Surgeon. Granted six months' leave of absence on surgeon's certificate of disability. S. O. 269, A. G. O., November 18, 1887.

ARTHUR, W. H., Captain and Assistant Surgeon. Granted two months' leave of absence, with permission to apply for two months' extension, to take effect on the arrival at Fort Niagara, N. Y., of Assistant Surgeon Paul R. Brown. S. O. 269, A. G. O., November 18, 1887.

KEAN, J. R., First Lieutenant and Assistant Surgeon. Granted two months' leave of absence, to take effect about December 1st. S. O. 269, A. G. O., November 18, 1887.

BROWN, PAUL R., Captain and Assistant Surgeon. Ordered to Fort Niagara, N. Y. S. O. 270, A. G. O., November 19, 1887.

SKINNER, JOHN O., Captain and Assistant Surgeon. Ordered to Fort Ontario, N. Y. S. O. 270, A. G. O., November 19, 1887.

RICHARD, CHARLES, Captain and Assistant Surgeon. Ordered to post near Denver, Col. S. O. 270, A. G. O., November 19, 1887.

CARTER, E. C., Captain and Assistant Surgeon. Ordered to Willet's Point, N. Y. S. O. 270, A. G. O., November 19, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 26, 1887.

NASH, F. S., Passed Assistant Surgeon. Detached from duty at the Smithsonian Institution, and ordered to the Washington Navy Yard.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 26, 1887:

	Cases.	Deaths.
Typhus fever	6	0
Typhoid fever	21	8
Scarlet fever	87	15
Cerebro-spinal meningitis	4	3
Measles	38	6
Diphtheria	149	48
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

"THE ADVERTISER."—Dr. Radcliffe Crocker, in hi introductory address before the University College Hospital, dwelt upon the subject of medical advertising; and he classified the advertising part of the profession on the principle Touchstone used in the gradations of quarrelling, and described humorously the "Advertiser Churlish" as the man who wrote works in which he made out everyone to be wrong but himself, professing to have made discoveries which the blindness and narrow conservatism of the profession prevented them from seeing or adopting, and who, when patients had been previously treated, depreciated directly or indirectly their former adviser in order to exalt himself. The "Advertiser Valiant" was a man who paraded his ability to cure obstinate or incurable diseases, such as consumption, cancer, etc., and ascribed his success partly to the fact that he was always ready to make the more serious diagnosis even in comparatively mild forms of diseases, and thus he was credited with curing phthisis, or whatever the disease might be, without really deserving it; further, even if he failed, he was always having a succession of new patients through his advertisements. The "Advertiser Quarrelsome" took the form of writing pamphlets against the abuse of various drugs in the treatment of disease, or against operative treatment in various surgical affections, and claiming to show how he avoided all such dangerous methods and yet cured his patients more quickly and safely. The last two were the "Advertiser Direct" and the "Advertiser Circumstantial." Pointing out that very few went so far as to advertise themselves directly, as they ran too much risk of being expelled from the profession, he described the "Advertiser Circumstantial," who, while appearing to praise something else, was really putting himself forward. As the most flagrant instances he mentioned men who lent their aid in puffing sundry trade-articles, either directly by writing testimonials to the vendors, or indirectly by allowing extracts from their works to be reprinted by the vendors of drugs, foods, or hygienic articles, and sent round as circulars or left in public places. Another plan was to write works known as "bread-and-butter" books, of more or less pretension, on common diseases, such as "gout," or some fashionable or new treatment, such as "massage," to give the impression that they were authorities on the subject.

HYDATIDS IN THE CAVITY AND SUBSTANCE OF THE HEART.—Dr. Rushton Parker, writing to the *British Medical Journal*, says that he was recently called in to see a little fellow, five years of age, whose life had suddenly become extinct within a few moments of his playing about in almost perfect health. He had once, two or three weeks previously, and again nearly a week ago, complained of a slight pain about the heart, but little notice was taken of a matter apparently so trivial. On August 1st he again made a similar complaint, and his father imagined that he felt the child's heart beating a good deal quicker, if not more vigorously, than it should do. However, he played about with his ball and helped his mother at the pump, and then sat playing on the sofa, when he suddenly uttered a scream, turned over on one side, and in a few moments was dead. On opening the pericardium the front wall of the right ventricle, near the base, was found bulged out by a hydatid, giving the appearance of another auricle. An incision was made into this, passing first through the ventricular wall, then through a tough adventitious sac about one-fifth of an inch thick, firmly adherent to the muscular substance, and rough inside like pericarditic lymph; the delicate mother-cyst within this contained fresh blood-clot and eight or more daughter-cysts (mostly pyriform or ovoid in shape, and varying in size from small currants to small beans), and had evidently attained a diameter of nearly one inch and a half before rupturing into the right ventricle; about the rupture the endocardium seemed rough and fibrinous. On raising the heart, and detaching it by cutting through the large vessels, there flopped out of the left auricle a simple hydatid cyst, measuring one inch and a half in diameter, which must have occupied almost the entire space of the auricle. No hydatids were found elsewhere, but only a superficial examination of the other organs was made.

Genius not a Neurosis.—Dr. Kiernan (*Alienist and Neurologist*) opposes the idea that genius, especially poetical genius, is a neurosis. He admits that many a matter-of-fact young man or woman in the emotional stage of insanity has composed respectable verses; but the power, instead of being sustained, is lost upon restoration to health. The subtile chain of associating power, which constitutes genius in its highest and best sense, differs decidedly from the di-jointed condition existing in paranœa. Huxley's phrase "the scientific use of the imagination," is strictly applicable to the highest poetic genius. Sophocles was summoned to court by his sons, when at a great age, to have him placed under guardianship as a dement; but upon his reciting to the judge a drama which he had just composed, the clearness of his intellect was so apparent that the case was at once dismissed. Fox, McCullough, and Bartley Campbell were paretic dements. After the disease set in their histrionic power vanished. Napoleon Bonaparte's epileptic insanity marred his work. The failure of the Russian campaign and most of his political blunders were the result of his suspicional delusions and epileptic stupor. Plato and Socrates were clearly victims of sexual perversion, and, like most sexual perverts, had a dreamy, emotional, pseudo-ethical sentimentality which led to the Platonic love idea in one case, and made Xantippe miserable in the other. William Pitt, the elder, suffered from acute gouty insanity, during which he was worthless as a statesman. Shelley and Cowper were victims of periodical insanity, which alternated with literary production. When Southey and Rogers fell victims of dementia, their poetry ceased to appear. Contrast the "Lady of the Lake" and "Bob Roy" of Walter Scott with his "Count Robert of Paris," and it is very easy to see which was penned when the brain was in full healthy activity, and which was written after poetic dementia had seized him. Genius is not a product of a morbid mind. Insanity, in its emotional stage, may touch the lips of a timid poet, but its song soon sinks beneath the disease.

The Treatment of Biliousness.—According to the *Boston Medical and Surgical Journal* the treatment of biliousness is prophylactic, alimentary, and medicinal. Prophylaxis is concerned with avoidance of all the known causes, whether of a toxic, malarial, or alimentary character. A plain diet, of bread, milk, oatmeal, vegetables, and fruits, with lean meat or fresh fish in moderation, and abstinence from alcoholic stimulants, seems to be the ideal fare for the biliously predisposed. This kind of diet is especially applicable for hot weather, when albuminoids are apt to clog the portal system, and pastries are an abomination, and when a broiled schrode, a little chicken or mutton broth, with bread and stewed fruit, will make a more healthful meal than the more sumptuous fare of a modern fashionable dining saloon. Exercise in the open air is of recognized utility in promoting oxidation and elimination, enhancing the digestive and assimilative processes, and lightening the burdens of the liver. Moreover, exercise (whether by rowing, horseback-riding, gardening, walking) hinders absorption of bile by the hepatic venous radicals, and promotes the passage of that fluid into the duodenum, through the increased compression exerted on the liver by the diaphragm and abdominal muscles; this is in accordance with a recognized physiological law. The victim of an acute bilious attack will generally get righted in a few days by, first, abstinence from all food, then a diet of porridge and milk, or skimmed milk alone, and a very gradual return to solid food, which for several days should be restricted to toast, a little lean meat, or broiled fish, with some succulent vegetables or ripe fruit. As for medicines, saline aperients, such as sulphate of soda, Epsom or Rochelle salts in full doses in the morning, or the now fashionable tumblerful of Hunyadi Janos will generally suffice to clear the *primæ viæ*; the latter has especially a reputation for evacuating bile. The striking relief obtained by free bilious evacuations has often been remarked, and the veteran transgressor resorts to his blue pill or podophyllin with every recurrence of his malady. Of late enonymin has come much into use as a cholagogue. Harley recommends to persons who seem to have a more than usual tendency to biliousness, traceable to sluggish biliary secretion, and where there seems also to be defective nerve action, small doses of nux vomica or strychnia after their meals. This may be combined with belladonna and aloes, as in the aloin, strychnia, and belladonna pill. The bilious person is generally constipated, hence such a pill has a special utility. Fothergill's pill of ipecac, capsicum, and pil. aloes et myrrh, has done good service in such cases. Nitro-muriatic acid and taraxacum have a reputation which is probably not altogether built on imaginary results. But bilious dyspeptics, while they should be attentive to the functions of eliminations (and doubtless the ancient predilection for purgatives has been justified by modern scientific research, which finds in intestinal septicæmias and alkaloids of putrefaction many of the evils formerly attributed to peccant humors and atrabiliary disorders), should aim especially to be good hygienists and learn to live right; but this is counsel which everybody gives and nobody takes.

The Consumption of Alcohol on Morality and Health.—The following statements made by M. de Flaix are deserving the consideration of students of the alcohol question. M. de Flaix says: "The birth-rate is less and the mortality greater in the departments where the consumption of alcohol is small; that neither crime nor suicide is in proportion to alcoholic consumption. Thus in the Seine-Inférieure the consumption of alcohol is three times that in the Nord; but suicide is only twice as frequent. In the Pas-de-Calais the consumption is twice as great as that of the Nord, while suicide is two and a half times less. In the Seine-et-Oise the consumption is one-half less than that of the Seine-Inférieure, but suicide in the former is twice that of the latter." Comparing different nations, he says: "France consumes less alcohol than the United Kingdom; its birth-rate is less, and its mortality, criminality, and suicide rates are greater. Italy consumes very little alcohol; its criminality is appalling (*effrayante*). Spain consumes three times less alcohol than Italy; its criminality is double. Sweden, Denmark, and Norway, with a population of about one-third, consume four times the quantity of alcohol consumed in Italy, and yet the criminality of the former is very small, while that of the latter is appalling (*effrayante*). Russia consumes four times the alcohol of France; its birth rate is almost double. Thus, all the hypotheses are upset; the most vigorous, the richest, and the most moral of the nations are those which consume most alcohol. The prediction that alcohol will destroy civilization and the human race is not supported by facts. If France, whose vitality is undergoing a crisis, were among the nations which consume most alcohol, she would serve as an excellent argument; but the consumption of alcohol by France is moderate, and it has been established already that those parts of France are the most vigorous where the consumption of alcohol is greatest."

The Nerve Influence in Pathology.—Dr. Meigs Case, of Oneonta, N. Y., writes: "In these days of 'blood-poisoning' and antiseptic surgery I would like to ask extremists if injustice has not been done in ignoring and neglecting 'nerve influence' and the solids. Practical observations upon the operation of blisters, emetics, snake-poison, or prussic acid, and of lock-jaw produced by a punctured wound or injury, afford a field for defenders of the ancient faith. Cocaine used in an extremity which has been prepared for operation by the Esmarch bandage, effectually cutting off the circulation, is another illustration grateful to the memory of old Dr. Chapman, of Philadelphia, and suggestive of the truth of solidism."

FOOT-AND-MOUTH DISEASE AS IT AFFECTS MAN AND ANIMALS, AND ITS RELATION TO HUMAN SCARLATINA AS A PROPHYLACTIC.

ALSO, REMARKS UPON THE TRANSMISSION OF HUMAN SCARLATINA TO THE LOWER ANIMALS, AND THE USE OF VIRUS THUS CULTIVATED AS A PREVENTIVE AGENT.

BY J. W. STICKLER, M.S., M.D.,

ORANGE, N. J.

The disease as it affects man.—It was long ago discovered that the human subject was susceptible to the contagium of foot-and-mouth disease. The disease is contracted in one of two ways, viz., by drinking milk obtained from cows affected with the disease, or by the accidental introduction of the virus into open wounds or sores upon the hands, or other parts of the body. In either case the systemic disturbance is, as a rule, very slight, while the local lesion, in the great majority of instances, consists of an inflammatory sore throat, with or without the development of small vesicles upon the inner surface of the cheeks, lips, and tongue. The cervical lymphatic glands are generally enlarged and tender. The tongue sometimes becomes swollen to a considerable degree. In some instances there has been an eruption of vesicles upon the feet and hands, in others a scarlet eruption has made its appearance upon different parts of the body. Hertwig,[1] during an epidemic of foot-and-mouth disease, drank daily for four days one quart of milk taken from diseased cows. In less than forty-eight hours he "began to experience slight fever, twitchings in the limbs, headache, a sensation of dryness and heat in the mouth, and an itching in the hands and fingers. These symptoms continued about five days. Then the entire mucous membrane of the mouth began to swell considerably, especially that of the tongue, upon which organ, particularly the edges of it, and also upon the inner surface of the cheeks and lips, there appeared small vesicles, never larger than a lentil, of a yellowish-white color, and filled with turbid whitish contents which were readily discharged when the vesicles were pricked, but were soon reproduced. Upon the following days the vesicles became still larger, and burst; the epithelium was then detached, leaving behind dark-red erosions which gradually healed. There was, conjoined with the above symptoms, a smarting pain in the mouth upon the attempt to masticate, speak, or swallow, and also an intense thirst. The vesicles upon the lips dried up, leaving in their places thin brown scurfs, which upon the tenth day after the appearance of the former fell off. Simultaneously with the development of the eruption in the mouth, numerous vesicles were formed upon the hands and fingers, which at first were of the size of a millet-seed, firm, and of a yellowish-white color, but in their further progress approximated in look to those in the mouth, healing, however, more slowly. At the termination of this process he was restored to the best of health." Two other physicians performed the same experiment upon themselves, with the same result as obtained in the case of Hertwig, except that they had no eruption of vesicles upon their hands. The symptoms thus produced by drinking fresh milk containing the contagium of the disease under consideration, vary somewhat from those produced by inoculation of the human subject with the contents of the vesicles, at least in some instances. That this is true will be shown in the record of the following cases:

About the end of August,[1] Mrs. X——, wife of an extensive farmer, came under my care on account of an eruption of *bright red spots*, one-eighth of an inch in diameter (covered with a thin white desquamation), which were so densely sprinkled over her body as to leave only minute interspaces of sound skin. As Mrs. X—— had within the last three years suffered from hepatitis with jaundice, I thought the eruption might be thus originated. Alterative purgatives made no impression upon the disease.

On a subsequent visit I found her husband complaining of a sore throat and mouth. Upon examination found the mucous membrane of his mouth, lips, tongue, and throat studded with small ulcers, giving off a white slough, which left behind a clean but highly sensitive cup-shaped cavity. His forehead was covered with an eruption similar to that upon the lower extremities of his wife. The eruption was never vesicular as it is in cattle. The spots made their appearance as slightly elevated, reddish prominences (papulæ), which gradually became bright red, then threw off a silvery-white scale, and gradually disappeared. Mrs. X—— had slight inflammation of the fauces. Some of the children about the house were also affected with sore throat, but the symptoms in these cases were very mild and easily overcome. At the time this disease affected the above patients the whole of Mr. X——'s cows had murrain. Mr. X—— says that, when examining one of the cows which was suffering from the disease, and while in the act of pressing back the lip, he observed two or three pimples on the upper lip to burst and eject the matter to a considerable distance, and that he received a portion on his cheek and hand. Both parties, as well as those affected in a lesser degree, had gone freely about the byres, handling the diseased cows, of which there were at times upward of a dozen ill at once, and the peculiar virulence of the symptoms in Mr. X——'s case seemed to depend upon the circumstance that the matter caught upon his hand and cheek was derived from one of the worst of the diseased animals. The epidemic of "sore throat" which occurred at Dover, England, in 1884, furnishes still greater opportunity for the study of "foot-and-mouth disease" as it affects man.[2] "During the early days of February, 1884, a remarkable outbreak of sore throat occurred in Dover, England, which, on account of the suddenness of the outbreak, the severity of the symptoms, and its chief prevalence among those occupying the best houses in the town, attracted no small amount of public attention, and naturally provoked a large amount of interest in the investigation as to the cause thereof. Controversy waxed warm, especially when it became known that the course of the epidemic corresponded most intimately with the track of a particular milkman, and that the milk supplied by this man was believed to be the vehicle of the specific poison occasioning the epidemic. . . . For the purpose of ascertaining what particular taint was present in the milk which was calculated to occasion this particular epidemic, a searching inquiry was made,

[1] Ziemssen's Cyclopædia of the Practice of Medicine, vol. iii., p. 521.

[1] Edinburgh Medical Journal, 1863, Hislop.
[2] Quoted from the official report of the epidemic.

and the following facts collected: The implicated dairyman obtained his supply of milk from twelve cows kept on his own premises at Dover, and also from three farm establishments in the country. All these places were visited and diligent search made for any evidence of the disease among either the cows or people living or engaged on the premises.

"At one of the establishments in the country it was found that aphthous fever had broken out among the stock on January 14th, and that milk from some of the affected cows was delivered to the Dover dairyman, and, after being mixed with other milk, distributed to his customers. Moreover, it was from this infected farm alone that the Dover dairyman obtained the supply of cream furnished to his customers. At the beginning of the inquiry it was stoutly denied that any of the milch-cows had suffered from disease, and a certificate from a veterinary surgeon and inspector to this effect was obtained and published. The matter was then referred to the police, and the truth gradually oozed out, until the facts as already stated were established beyond dispute; then the farmer not only admitted the fact of the disease among the milch-cows, but confessed to the sale of their cream and milk in Dover, not only to the dairyman whose milk was especially implicated, but also to another milkman, on two separate occasions, among whose customers a second simultaneous outbreak occurred; thus a second experiment was performed with this tainted milk among another set of individuals, with like results to the first, contributing additional evidence of the presence of poison in the milk supplied from the infected farm. Thus it was clearly established that the sufferers in this epidemic partook of milk which had been secreted by cows suffering from foot-and-mouth disease. During the week ending February 9th, two hundred and five persons were attacked with this disease. The majority of persons who suffered during the Dover epidemic presented two prominent symptoms in common, viz., *inflammatory sore throat and enlargement of the cervical lymphatic* glands; but the lesions produced varied considerably in different cases. The vesicular eruptions were followed either by a raw, red, œdematous appearance of the mucous membrane, or white patches, and the ulcers which supervened assumed in many instances a chronic character, with thick, puckered edges, and were a long time in healing. When the inflammation went on to suppuration recovery was much slower than after common quinsy, and the enlarged cervical glands remained tender, red, and swollen long after the throat symptoms had subsided, *resembling in this respect the sequelæ of* scarlet fever. Erysipelas and purulent formations were also concomitants of the epidemic. In some instances the feet of those who suffered were swollen and painful, simulating rheumatism; and in one instance eczema occurred between the toes of the feet, the affection being accompanied with very fetid exhalation. A fatal termination resulted in the cases of two children who had very bad throats and mouths, with the extension of the disease to the respiratory tract, their deaths being, in the opinion of the medical attendant, due to the poisonous effects of the milk. Two persons, who labored under chronic kidney disease, were respectively attacked with sore throat and died on the same day; other people in the same houses suffering also from the epidemic sore throat."

Having thus traced the course of foot-and-mouth disease as it occurred in the cases quoted, and thinking it manifested a certain resemblance to human scarlatina, I asked Dr. M. K. Robinson, medical officer of health of East Kent, England, if he would call upon the various persons who had been affected with the "epidemic sore throat," and ask them whether they had had scarlet fever either before or after having the "sore throat" in 1884, my object being to determine whether the human system, having been attacked by one of these diseases, would, as a result, become fortified against the contagium of the other.

TABLE.

Incidence of Scarlet Fever among Persons who Suffered from "Epidemic Sore Throat" due to Use of Milk derived from Cows Suffering from Aphthous Fever, which Epidemic occurred in Dover in 1884.

No. of case.	Scarlet fever previously.	Scarlet fever since.	Remarks.
1	.....	.....	Four other members of same family, who had previously had scarlet fever, escaped epidemic of sore throat.
2	.....	.....	
3	.....	.....	
4	.....	.....	Five other members of this family, who had previously had scarlet fever, escaped throat epidemic.
5	1	.....	
6	.....	.....	
7	.....	.....	Two members of same family, who had previously had scarlet fever, escaped throat epidemic.
8	1	.....	
9	.....	.....	
10	1 ?	.....	Believed to have had scarlet fever with other members of family when young.

These statistics were gathered two years after the outbreak of the "sore-throat epidemic" in Dover. During this interval of two years 22 of the patients changed the place of their residence and could not be found, with but few exceptions, and from these few it was impossible to secure replies. The tabulated facts concerning the remaining 183 persons show:

1st. That *none* of the persons affected with the "throat epidemic" have since had scarlet fever, *i.e.*, had not had it at the time they were questioned.

2d. *That members of eight families who had previously had scarlet fever escaped the "throat epidemic,"* while the remaining portion of the households developed the disease.

3d. That 16 persons affected with the "throat epidemic" had had scarlet fever.

4th. That 4 of the 16 persons who had had scarlet fever had a *mild form* of the "throat epidemic."

5th. That of the affected individuals 2 had had scarlet fever *when young*.

6th. That 10 of the cases were doubtful whether they had previously had scarlet fever.

May it not, therefore, be possible:

1st. That the affected persons have not since had scarlet fever because of the protective influence produced by the "throat epidemic."

2d. *That the members of certain households who had had scarlet fever had thereby secured immunity from the "throat epidemic," as indicated by the fact that they escaped.*

3d. That in four of the instances in which scarlatina had antedated the "throat epidemic" there was a partial protection afforded, as indicated by the fact that four of these cases were mild.

4th. That in those instances in which scarlatina had occurred in early youth the protection had become exhausted.

5th. That these two diseases may be for a time mutually protective.

It is certainly a remarkable fact that, in twenty-four or more instances, the throat epidemic failed to attack those who had already had scarlatina; also, that the few attacked with the throat epidemic who had had scarlatina, had, in one-fourth of the instances, a mild type of the epidemic disease, indicating, possibly, that the system had been so affected by the scarlatinal contagium as to become less susceptible to the virus of foot-and-mouth disease. That a certain number who had previously had

scarlet fever were attacked by the "throat epidemic," is not strange, for it sometimes happens that an individual will have two attacks of scarlet fever, with, in some instances, only a short interval of time between the attacks. On the other hand, it may be true that the twenty-four or more individuals who had had scarlatina, and escaped subsequently the sore-throat epidemic, were not susceptible to the influence of the contagium which the infected milk contained. As is very well known, there are some persons who, though many times exposed to the poison of small-pox, measles, or scarlatina, remain unaffected by such exposure. In considering the facts before us I think this truth should have its share of thoughtful attention.

Believing, however, that in the evidence furnished by the "Dover epidemic" there was an indication of what might possibly be accomplished by the use of the virus of foot-and-mouth disease as a preventive of human scarlatina, I made further experimental investigation, as follows:

With some virus (contents of vesicles) taken from cows having a mild form of foot-and-mouth disease, I inoculated three children, and subsequently exposed them to scarlet fever contagium. The histories given briefly will show the results:

Case I.—M. M——, about eight years of age; had never had scarlet fever. On January 12, 1884, I injected under the skin of his arm a small quantity of the virus. A short time thereafter the cervical lymphatic glands became enlarged and tender to the touch. There was no marked systemic disturbance, neither was there any sore mouth or throat. All signs of glandular enlargement and tenderness had disappeared in six or seven days. He was then taken to a house in which there was a boy sick with scarlet fever. The disease was in the desquamating stage and the throat still sore. His parents being poor, the pillow upon which the patient lay had not been exchanged for a clean one since the beginning of the sickness. This pillow was placed over the face of the boy who had been inoculated, and held there some time. He was then made to inhale the breath of the patient, and afterward to remain some time in the sick-room. The boy did not develop scarlatina after having been thus exposed, neither has he contracted the disease since, although there has been opportunity for infection.

Case II.—B. P——, aged four years; had never had scarlatina. On March 6th I inoculated her in the arm (hypodermically) with a small quantity of the foot-and-mouth virus. On March 13th her temperature rose to 103° F. Her mouth was sore, without showing any vesicles, and she complained of a pricking sensation in her throat. She had slight headache, the appetite was impaired, and she was quite peevish. There was no eruption at any point on the body. By March 20th she was well. She was then taken to a house where I had a patient in the desquamating stage of scarlet fever. The patient was very sick at the time because of complications; indeed was so ill that I was somewhat doubtful about the issue. The same plan of exposure was adopted as in the first case, although I could not succeed in getting the inoculated child quite near enough to the patient to inhale her breath; but the "pillow exposure" and the length of time she remained in the sick-room afforded a good opportunity for infection. She did not subsequently develop scarlet fever.

Case III.—J. M——, aged about ten years; had never had scarlatina. I inoculated him just as I did the first two. He did not afterward develop any systemic disturbance or local lesion. After a lapse of three years, with opportunity for infection, he tells me he has not had scarlatina.

The results thus obtained, especially when taken in connection with the data furnished by the statistical table, *seem* to furnish some reason for believing that, for a time at least, the virus of foot-and-mouth disease is protective against the contagium of human scarlatina. But I am well aware that at this stage of the investigation *conclusions* cannot, ought not to be advanced, and until further information can be obtained by careful experimental investigation, nothing absolute or positive should be said concerning the practical issue above alluded to. While foot-and-mouth disease, as it affects man, is in many respects the exact counterpart of the disease as it occurs in cattle, yet there are certain points of difference, and in order to make them apparent a brief description of the latter affection will be given. The disease (as it affects cattle) may be defined as a very contagious and infectious affection, characterized by an eruption of vesicles or blisters in the mouth, on the internal surface of the lips, sometimes in the nostrils, on the teats and udder, between the pedal digits and around the coronets, and sometimes in the lactiferous ducts. It passes through four different stages, viz.: fever, eruption, ulceration, desiccation and desquamation. The symptoms of these four stages or periods are as follows:

First Period. Before any perceptible alteration has taken place in the ordinary habits or condition of the animal, the thermometer indicates an increase of temperature, which generally ascends to 102°, and as high as 104° or even 107° F., in from one to two days, and does not descend to any extent until the end of the eruptive period. The next indication is dulness, inappetence, and slight shiverings. The muffle becomes warm and dry, the eye is tearful, and the mouth hot and inflamed-looking in places, and frequently sore when handled, the membrane being covered with viscid mucus, which flows in stringy masses from the lips. There is grinding of the teeth, and a smacking or clicking noise; the breath has a fetid odor; rumination ceases, and the prehension, and often the deglutition, of food is painful, the animal preferring to dabble its mouth in cold water. Not infrequently, when the feet are beginning to inflame, the animal stands uncomfortably, drawing the limbs together, or jerking them up suddenly under the body, arching the back, and pawing; the movements are reluctantly performed, and the coronets hot and sore. There is also slight constipation, and, if with a milch-cow, the secretion of milk is gradually diminished, and that fluid assumes a yellow tint; in the majority of cases it is nearly or altogether suspended. *The udder becomes red and tense* when it is involved, and the teats swollen and painful to the touch. This stage usually lasts from twenty-four to forty-eight hours, according to the intensity of the fever.

Second Period. After the time above mentioned the eruption begins to appear in those parts which are to be its seat, and the fever commences to abate in many cases. When the mouth is chiefly affected there are seen on its lining membrane, and particularly on the upper lip, gums, and sides of the tongue and palate, white or yellowish-white blisters, the size of a grain of millet to that of the size of a pea or nut, their form being very irregular. Sometimes they are discrete, or scattered over the surface; in other cases they are confluent, collectively forming patches which are at first gray or yellow, and afterward white; slightly convex; each vesicle is usually circular; the smallest are seen on the muffle. In the mouth they are largest, and most frequently confluent; but there they only exist for a brief period, the friction caused by the movements of the tongue tearing them; the epithelium is detached in flakes of variable dimensions, leaving unhealthy ulcers or denuded spots, or "erosions" of a bright red tint, which contrasts markedly with the gray hue of the surrounding surface. These shreds are often seen adhering to the border of these sores; and if on the tongue, that organ is kept continually moving to get rid of them, and the animal emits a smacking sound with its lips. At this stage of the disease the papillæ of the tongue are congested and prominent. Where there is no friction the vesicles do not rupture within one or two days. On the udder the vesicles are somewhat different. *The teats are most frequently their seat*, and it is not unusual to

find the phlyctenæ grouped in a circle around their orifice; when isolated on the surface of the organ they are surrounded by a pale-red circle, and when confluent they are very irregular and variable in number. In the case of a cow the alteration of the milk is very striking. It coagulates on being boiled, or when its temperature is only slightly raised. It also becomes yellow in color and acid in reaction.

When the limbs are affected the heat and redness of the coronet are most noticeable toward the heel and interdigital space of one or more feet. The coronet swells; the animal is lame, and prefers to maintain a recumbent position. In one or two days the vesicles are developed at the points indicated, most frequently earliest in the interdigital space; at first they are small, but they increase in size until they are as large as a bean or small nut, and extend round the claws, often becoming confluent, the contents appearing as a yellow limpid fluid. The skin of the part assumes a bleached aspect, and is soon covered with a kind of cheesy matter, resulting from the inspissation of this fluid, which emits an ammoniacal odor. In some cases the skin around the base of the horns becomes inflamed at the same time as that of the mouth or feet, and the horns are loosened. Occasionally, also, a vesicular eruption manifests itself at the orifice of the vagina, at the perineum and anus, or in the nostrils; and it sometimes happens that the eyes are affected, the conjunctival membrane becoming inflamed and suppurating, and phlyctenæ forming on the cornea. There may also be nasal catarrh and symptoms of gastric derangement.

Third Period. This is the aphthous stage of the disease, and begins when the vesicles have ruptured, and, the epidermis being removed, erosions appear. This does not occur everywhere at the same time, but varies according to the region. In the mouth it soon occurs, owing to the movement of the tongue, and also in the feet by that of the claws. On the udder it is later, seldom occurring before thirty-six or forty-eight hours; or if the disease is benignant the vesicles on this organ may not rupture at all, their contents becoming absorbed, and the pellicle of epidermis covering them scaling off when cicatrization has taken place beneath. When the vesicles do break, there remains a little, bright-red sore, which is smooth or granulating, and is soon covered with a fluid pus mixed with epithelial cells, which in drying forms a thin reddish crust that protects the erosion until it heals. In the mouth and on the lips the vesicles are broken almost as soon as formed, leaving circular or irregular bright-red sores which bleed readily, their rupture being indicated by dribbling of saliva streaked with blood.

It sometimes happens that when the tongue is seized to explore the mouth, large patches of epidermis come away in the hand, as if the tongue had been boiled. In some rare cases an exudation of yellow color and cheesy consistency is observed toward the root of the tongue, due to epithelial proliferation.

The fever has greatly subsided, but the thirst is intense, and the animal eagerly drinks water or gruel, though, owing to the soreness of the mouth, it can eat but little, especially if the food be dry and hard; consequently the loss of condition is rapid.

Fourth Period. This is marked by the desiccation or drying up of the aphthæ, and the formation of new epidermis. The crust falls off, and new epidermis or epithelium appears as a thin, lead-colored pellicle. There is also at this time a general desquamation of the cuticle, and this is invariably the case. There is also a good deal of itching of the surface (Walley). With the completion of these processes all traces of the disease disappear. There is no lameness, the appetite has returned, and the former condition is being restored; while the secretion of milk, which may have been greatly diminished—perhaps to less than one-third—becomes augmented, and regains its normal properties.

Bollinger states that "in animals which have once acquired the disease the susceptibility ceases for a considerable period, or at least becomes very slight. Repeated attacks of the malady in the same animal are, upon the whole, rare." That the susceptibility ceases for a time has been demonstrated by Dr. E. Klein, of London, England. He inoculated five sheep with active cultivations of the micrococcus, but without producing any definite local or general lesion. "Subsequent feeding of these same sheep with the active micrococcus had no result." From this he argues that a previous subcutaneous inoculation with the micrococcus provides the animals with immunity against the disease. Dr. Klein also claims to have discovered the germ peculiar to this disease. His method of investigation was as follows: He inoculated alkaline peptones, broth, and solid agar-agar, peptone broth mixture, solid nutritive gelatine mixture, and milk, with lymph which was obtained from the vesicles of diseased sheep. He discovered, after a few days, a thin film, limited in extent, upon the surface of the solid media at and near the point of puncture. The film gradually spread, presenting a very characteristic appearance, namely, *a collection of closely packed minute granules* or droplets. These enlarge slowly and gradually, and become whitish and translucent in character. If the point of a needle or platinum wire be moistened with the lymph and pushed into the solid medium, the line of puncture becomes marked as a linear aggregation of minute granules or droplets after several days or weeks. There is also, in addition to this, on the surface of the culture media the film of granules already alluded to, which starts from the point of inoculation. This micrococcus grows very slowly, the first indication of its growth in solid nutritive gelatine mixture, at a temperature of 18° to 22° C., becoming visible under a lens at the end of from five to eight days, or still later. The growth thus developed appears in the form of a small cluster of transparent granules. In agar-agar mixture, kept at 35° to 38° C., the growth is sooner visible, although, after six or seven months, "in all media and under all conditions the growth remains of limited extent." When milk is inoculated with the micrococcus, and kept at a temperature varying between 35° and 38° C., the growth is found to progress very slowly. The condition and natural appearance of the milk are not changed. No curdling occurs, but the reaction becomes acid. The micrococcus forms in artificial media dumb-bells (diplococcus) and beautiful chains (streptococcus). These vary in length according to the number of micrococci composing them, "the short chains being a linear series of four, six, or eight micrococci, the longer ones of more than eight up to thirty and more micrococci." The longer chains are always curved, and even convoluted.

The above-mentioned characteristic appearance of the growth is owing to the presence of smaller or larger masses of chains matted together. Subcutaneous inoculation with artificial cultivations produces no perceptible disorder, but by feeding sheep with a twentieth generation the typical disease has been reproduced, viz., vesicles and ulcerations upon the feet. From the vesicles of such animals lymph was obtained which, on cultivation, yielded the same micrococci, characterized by the same slow growth and the same typical appearance as those used for the experiment. Dr. Klein claims, therefore, that there can be no question about the identity of this peculiar micrococcus with the cause of the disease.

The description thus given of the mode of growth and appearance of the micrococci of foot-and-mouth disease does not materially differ from that given, by the same investigator, of the micrococci found in the ulcers of cows affected with a disease which has since been determined to be cow scarlatina. For the sake of instituting a comparison, I will quote his own words with reference to the cultivation and appearance of the bovine scarlatinal streptococcus.

"From the deeper parts of an ulcer of cow IV. (one

he had under observation) material was obtained, with which tubes containing either solid nutritive gelatine or agar-agar mixture were inoculated. After some days, and in both media, a micrococcus appeared, the growth of which was extremely characteristic. These are its characters in the nutritive gelatine: After three to six days' incubation at 20° C., the growth made its appearance at the point or line of inoculation, in the form of small points or granules, whitish in color, and tolerably closely placed. During the next few days their number and size increased. At the end of a fortnight the line of inoculation was visible as a streak of whitish granules or droplets, some large, others small, more or less closely placed. On the surface of the gelatine the growth, like a film of granules, spreads slowly in breadth, but even after months remains small. When inoculated into the depth of the gelatine the channel of inoculation becomes visible as a whitish streak, made up of smaller and larger droplets. The gelatine is not liquefied by the growth. The same characters are assumed by the growth in agar-agar mixture, and in solid serum. The general aspect of the growth in gelatine, in agar-agar, and in serum, is very similar to that presented by the streptococcus of foot-and-mouth disease, but with this difference, namely, that in gelatine tubes the streptococcus of foot-and-mouth disease is a little faster in its growth, and its component granules are a little more distant. Nevertheless, I have tubes of both kinds of organisms in gelatine, and in agar-agar tubes, which cannot be, from their general appearance, easily distinguished. In faintly alkaline broth, or in broth and peptone, the micrococcus of the cow ulcers grows readily, and in the same manner as that of foot-and-mouth disease. But there is one test by which the two kinds of organisms can be very readily distinguished: the streptococcus of foot-and-mouth disease, when grown in milk, does not affect the fluid character of the milk, whereas milk inoculated with the organism obtained from the cow ulcer will, if kept for two days in the incubator at 35° C., have been turned completely solid. This difference is a very striking difference, and a few days' growth in milk suffices for distinguishing without fail between the two. The microscopic examination of a culture in broth peptone, in gelatine, or in agar-agar mixture, shows that the growth consists of spherical micrococci, arranged as diplococci, and as shorter and longer straight, wavy, or curved chains—streptococcus—these latter sometimes of great length. As regards the shape of the micrococci, the mode of their division, the branchings of the chains, the presence here and there in the chain of a large element among the smaller ones, the organisms of the ulcers hardly differ from the description which I am preparing of the streptococcus of foot-and-mouth disease."[1] It will be observed that the only point of real difference is the effect the growth of the streptococcus of the cow ulcer has upon milk, solidifying it, while the streptococcus of foot-and-mouth is asserted not to produce this effect. In connection with this point the following may be quoted: "But there is one point in which, so far as I know, it (the milk) differs from all other milk, and that is in its coagulation on being boiled, or having its temperature only slightly raised by being mixed with hot gruel," etc. (*Edin. Med. Journal*, 1863, p. 711). "It is a very general opinion among continental veterinarians that, when the milk can be boiled without coagulating, it is no longer dangerous to use; and Hilderbrandt, in Magdeburg, expressly states that he never observed a single case of injury to health from the use of milk which had been boiled without coagulating" (*Gurlt u. Hertwig's Magazine*, vi., p. 179).

It is certainly true that the two diseases ("foot-and-mouth disease" and the "Hendon cow disease") are very similar in some of their clinical features. This will be made manifest when the mode of development and subsequent history of the vesicles which are characteristic of the two diseases shall have been compared. In the following notes some points of similarity between these two affections may be incidentally noted.

When at Deering, Me., some time ago, for the purpose of studying foot-and-mouth disease in cattle, I saw one or two cases which could very easily have passed for "bovine scarlatina," as described by Drs. Klein and Cameron. The vesicles and ulcers upon the teats and udder were the exact counterpart of the word-picture of those seen upon the Hendon cows' udders and teats.

Just here I may say that during the last four years I have been endeavoring to determine: 1st, Whether scarlatina can be generated in the lower animals by inoculation with human scarlatinal virus; 2d, if so, whether such a disease is mild in character; 3d, whether virus furnished in such a manner could, by inoculation, be used as a means of preventing the development of scarlet fever in human beings.

To determine the truth concerning the first inquiry I obtained some blood from a patient who had scarlet fever, and injected thirty drops of it into the right jugular vein of a colt about one year old. I also introduced under the skin of the thorax a blood-clot obtained from the same patient, and caused the colt to swallow about two drachms of pharyngeal mucus. This occurred on May 1, 1883. The temperature gradually rose from 101¼° F. (the temperature of the colt before inoculation) till it reached, on May 12th, 102⅕° F. During the following night the colt lacerated the skin of the chest to a small extent, and immediately thereafter the temperature began, or continued to rise till it reached 103½° F., at 8 P.M., May 13th. The temperature then began to fall, till it stood at 101¼° F., May 16th, 3 P.M. During this time the intermaxillary glands became enlarged and sensitive, the mucous membrane of the nostrils and eyes injected, and from the nostrils there was a discharge of ropy mucus. Thinking that the injury received on the 12th might have interfered with the natural action of the virus by causing a local inflammation and a general rise of temperature, and wishing, if possible, to intensify the effect of the first inoculation, I injected into the jugular vein some pharyngeal mucus from two well-marked cases of scarlatina. The result was an increased redness of the mucous membranes of the nose and mouth, and a mild sore throat, which disappeared with the fading of the redness of the mucous membranes. The symptoms above given almost entirely disappeared by May 24th. There was no subsequent œdema of the extremities or sheath, nor was there any desquamation of the cuticle.

On June 28, 1883, I enveloped the head of a perfectly healthy colt in a bag containing a chemise which had been worn by a scarlet-fever patient. This I allowed to remain adjusted about seventy-two hours. On July 2d I injected into the left jugular vein, and into a vein of the leg, some human scarlatinal blood. Within forty-eight hours the temperature began to rise, the colt became less active, showing a tendency to remain quiet. On the sixth day (July 8th) she began to cough and swallowed with difficulty. The visible mucous membranes were quite red, and at certain points had somewhat the appearance of the mucous membrane of the pharynx in man when affected with scarlet fever. The intermaxillary glands were enlarged and sensitive, and, when the throat was pressed upon, the colt evinced uneasiness. There was a discharge of tenacious mucus from the nostrils. The pharynx was unnaturally red. On July 9th I introduced some epidermal scales, obtained from a scarlet-fever patient, under the skin of the abdomen, but so far as I could determine they produced no effect. In this case there was a desquamation of the skin at a few points where I had not previously seen an eruption.

In both colts there followed the inoculations sore throat, redness of the mucous membranes of the nostrils,

[1] Report on Milk Scarlatina to the Local Government Board, by Dr. E. Klein, London, England, 1886.

mouth, and pharynx, elevation of temperature above the normal, and in one, desquamation of the cuticle. It seems reasonable, therefore, to believe that a specific disease was produced in both instances, and that the specific disease was scarlatina. Since that time I have inoculated rabbits, dogs, guinea-pigs, and cattle with human scarlatinal matter, and have obtained some very gratifying results, especially in cattle. In May, 1883, I inoculated a calf with human scarlatinal virus by injecting into the general circulation some blood taken from a well-marked case (a young man with a typical eruption on neck, chest, abdomen, and limbs), and by subcutaneous introduction of the blood into the abdomen. After the lapse of a few hours the skin at and near the point of inoculation (abdomen) became uniformly reddened. The elevation of temperature was very slight. The redness and sensitiveness of the skin increased till May 24th, when I discovered pus at the centre of the area of redness. The temperature at that time was 102⅕° F. The visible mucous membranes were not affected. Recovery complete by June 1st.

Knowing that cows recently calved were supposed to be especially susceptible to scarlatinal contagium, I procured one that had aborted about one week prior to the time of purchase. I inoculated this cow in the udder with some pharyngeal mucus taken from a patient sick with scarlet fever. The day following the inoculation the temperature rose to 102° F. Pulse, 48. On the third day the temperature was 102⅗° F. Pulse, 56. The temperature then began to descend till it reached 101¼° F. on the eighth day. During this time a cough developed, and it was noticed that the animal did not swallow with the same readiness as usual. At the point of inoculation had developed a superficial vesicle, which very soon became filled with purulent contents. Still deeper in the tissues a small abscess formed, which, after discharging its contents, remained open, discharging a small amount of pus. The skin around the seat of the vesicle and abscess was quite intensely reddened. The temperature gradually declined, till finally, on the nineteenth day, it fell to 100¼° F. There was a desquamation of the cuticle near the abscess where the skin had been reddened.

The next cow I inoculated was in the third or fourth month of gestation. The inoculation was made in the udder, and with pharyngeal mucus from a typical case of human scarlatina. Twenty-four hours after the inoculation the temperature began to rise, although slowly. On the second day the thermometer showed a temperature of 101½° F., and it did not vary from this point till the seventh day, when it fell to 100° F. During this time the udder became reddened, swollen, and tender, and finally suppurated at the point of inoculation. After the pus, which was small in quantity, was allowed to escape, the cavity of the abscess continued for a few days to discharge pus and then gradually healed. There was no sore throat, nor alteration of the mucous membranes. The reddened integument of the udder around the abscess desquamated. A subsequent inoculation of this cow with human scarlatinal virus produced no effect.

I next inoculated a calf with pharyngeal mucus and epidermal scales derived from scarlatinal patients. The inoculation was made in the abdominal region. At the point of the inoculation there very soon appeared a vesicle about as large as a lima bean, which was at first quite clear, but later became filled with sero-purulent matter, and then became yellow in appearance. Coincidentally with the development of the vesicle there was an elevation of temperature, and the appearance of an intense redness of the skin for some distance from the point of inoculation. There was no sore throat. As I wished the contents of the vesicle as a virus with which to inoculate some children, I punctured it, collecting the fluid in a small bottle. After being punctured the vesicle became converted into an ulcer, which gradually healed. The skin near this vesicle desquamated after the redness disappeared. I am led to believe, as a result of what I have seen while experimenting thus with cattle, that it is possible to infect them with human scarlatinal contagium.

To answer the second question, I may say that, so far as my experience serves me, the lesion produced in the lower animals by inoculation with human scarlatinal virus is a mild one. I am aware, however, that it *might* be otherwise.

In a recent letter Dr. E. Klein, of London, England, whose reputation and skill as an investigator place him very high in our esteem and confidence, tells me that cows inoculated with scarlatinal micrococci of human source become affected in *precisely* the same manner as the Hendon cows had been. The disease he refers to has the following characteristics, viz.: Upon the teats and udder vesicles or bullæ appear, from five to seven days after the commencement of the disease. In number they vary from two to four on a teat, and range in size from a pea to a horse-bean, and contain at first a clear fluid. The first vesicle frequently appears between the two foreteats, close to the abdominal vein. These vesicles usually become broken in milking, leaving raw sores, sometimes red, in other cases pale in color, with raised, ulcerated-looking edges. Shortly after the vesicle becomes ruptured a brown scab forms upon the sore. A thin, watery fluid exudes from under the scab. The skin about the eyeballs is puffy, and is said to present a minute red eruption or rash. There is also an eruption on the hind-quarters. This eruption in its later stages consists of patches of eczematous-looking crusts, which, when picked off, leave a raw, moist sore. The hair comes away with the scab. There is no pitting of the skin. There is sometimes a discharge of yellow matter from the nostrils and eyes. The fever is moderate. Sore throat is said to occur in severe cases. The bowels are loose in very acute cases. There is a dry, husky, irritative cough, with bronchial râles and quickened breathing in some cases. In December, 1885, it was reported that a sudden and extensive outbreak of scarlet fever had occurred in South Marylebone, and that it appeared to be associated with the distribution of milk from a particular retailer. It was afterward discovered that the milk was obtained from cows affected with the disease just described. There was in all about one hundred cases of scarlet fever caused by drinking the infected milk. If, then, it be true that the Hendon cows furnished a contagium which caused the development of genuine scarlatina in about one hundred persons, it must be true that the cows had scarlatina; and again, if the inoculation of cattle with human scarlatinal virus produces a disease identical with the Hendon cow disease, it follows that scarlet fever can be generated at will in susceptible animals.

I have found that results I obtained in several instances are greatly strengthened by the recent experimental investigations of Dr. Klein as to the nature of the Hendon cow disease, and its connection with the outbreak of scarlet fever at South Marylebone and in a certain district in London. The vesicles upon the udder of the cow and the abdomen of the calf already alluded to, as well as the general course of the disease, as occasioned by inoculation with human scarlatinal virus, correspond with the description of the disease as seen in England.

The answer to the third and most important question may perhaps be suggested in what follows:

In the early part of the year 1883 I inoculated twelve persons with virus obtained from horses supposed to have scarlatina. Since that time not one of that number, so far as I can learn, has had scarlet fever. These twelve persons were also inoculated with human scarlatinal blood after they had been inoculated with equine virus. During the summer of the same year I inoculated thirteen children, all of whom had been, and were at the time of inoculation, exposed to the influence of air contaminated by the breath and exhalations of scarlatinal

patients. Five of this number escaped, the remaining eight developed the disease (scarlatina) very soon after inoculation, in one instance within five hours. Four of the eight cases had no angina, but simply the eruption, with slight disturbance of the stomach. They were not confined to bed one hour. None of the cases were severe. During the last year I have inoculated two children with the contents of a vesicle produced in the abdomen of a calf by inoculation with virus derived from a patient who had scarlet fever. The notes of the first case are furnished by Dr. Stubbert, of Bloomfield, N. J., who watched the patient from day to day after the inoculation. "On April 25th the child was inoculated in the left arm with scarlatinal matter taken from a calf. On the 27th an erythematous blush appeared about the scarification. By the 28th the blush had disappeared, but a scab had formed, and around its puffed-up border there was a red areola. On April 30th the child had quite a high fever. On May 1st there appeared on the upper part of the chest a rash similar to a scarlatinal rash. On May 2d the scab came off. The rash which began upon the chest spread to the arms. On May 3d the rash was less bright, and on the right shoulder there was evidence of a slight exfoliation of the skin. In three or four days after this the child was restored to perfect health." The second child was inoculated in the presence of Dr. Stubbert, who kindly permitted me to test the virus not only in this, but in the previous instance. The only result I obtained in this second case was a slight erythematous blush, which, after existing two or three days, gradually disappeared. There was no systemic disturbance. With scarlatinal virus modified by transmission to the cow, I inoculated two other children, producing in them a distinct local lesion. These children have not since developed scarlet fever, although the disease has existed in their immediate neighborhood, and they have been more or less exposed to its influence. While the subject-matter of this paper thus presented to you does not furnish a positive answer to the question, "Can we prevent the development of scarlet fever by the use of virus obtained in one of two ways, as indicated above," it does offer some truthful statements which suggest an answer, and which, I trust, will incite the profession to aid me in the further prosecution of this very interesting and important line of investigation.

Dr. Squibb on Veratrum Viride.—Dr. Squibb, in his *Ephemeris*, says that veratrum viride is more used by country practitioners than by those living in the cities, and thinks this indicates its value, as country practitioners would not continue to use it unless they saw that it produced good results ; and he does not hesitate to set their experience against the theoretical objections of certain authors. He considers it a potent and fairly manageable arterial sedative—better than aconite, in that it reduces the force and rapidity of the heart's action more powerfully and more promptly. He advises using the fluid extract, and administering two minims every three hours, in a little water, and increasing to three minims at the third dose, if no effect is perceptible at that time. This is the treatment for ordinary cases. When a rapid effect is desired, from four to six minims may be given every hour or two until the pulse-rate falls to fifty or sixty beats per minute, when the dose must be lessened and the intervals lengthened, so as to keep the pulse just as it is wished. Owing to the uncertainty of its absorption from the stomach, either the fluid extract or the tincture of veratrum viride may be given hypodermically. In grave cases, from eight to ten minims of the fluid extract, or double this dose of the tincture, may be given every fifteen minutes at first, and then every half-hour until the pulse-rate falls to sixty beats per minute ; after which the smallest dose which will keep it there must be used.

ON THE EFFECT OF HIGH ATMOSPHERIC PRESSURE ON THE EAR.

By SAMUEL SEXTON, M.D.,

NEW YORK

The effect of subjecting the ears to high atmospheric pressure differs, when gradually accomplished, from the sudden concussion of explosives, as by the blast of great guns or boxing the ear. The injuries under discussion mostly arise from going into submarine caissons, though submarine divers and travellers rapidly transported to high altitudes often experience unpleasant aural symptoms from this cause. The writer has had frequent opportunity for studying the effect of undue atmospheric pressure on the ear since the construction of the Hudson River Tunnel was commenced, some seven or eight years ago, a number of the employés having come to his aural clinic at the New York Eye and Ear Infirmary on account of the injury done to their ears. It is well known that the atmosphere in which we live has a pretty uniform pressure upon the body of sixteen pounds to the square inch. Now, any decided variation from such tension is liable to give rise to discomfort, and this is just what takes place in submarine caissons, where the pressure is sometimes four or five times greater. Persons about to be subjected to the greatly increased aerial pressure of a caisson are prepared for it gradually by means of a so-called lock, or air-tight chamber, which they enter and occupy until enough compressed air is gradually forced in to enable them to pass on into the working-chamber, where pressure is maintained as in the lock, namely, twenty to forty pounds, or more, to the square inch. The practical information obtained by the writer on this subject from one who had worked in the Hudson River Tunnel for two years and eight months is of interest. His informant, an Irishman, had worked about one-half of the period above mentioned under a pressure of about twenty-six pounds to the square inch, but often under much greater pressure. At the Jersey City terminus, where he was employed, more pressure was required in tunnelling than at the New York end. The atmosphere was always humid, and the workmen were obliged to stand, while freely perspiring, in more or less water, which everywhere was oozing in. He stated that his ears were never affected, nor were his son's, though the latter commenced to work in the caisson four years ago, at the age of fifteen years, and remains there up to the present time. He and his son are both of them healthy and sober. They have been well while working in the tunnel, neither of them ever having had the "bends." He relates that he could whistle under a pressure of twenty-four pounds—a difficult feat, it would seem, since possible to but few even under a pressure of twenty-two pounds.

It may be premised here that were healthy and sober men, free from pre-existing aural trouble, only employed, there would be much less suffering from ear, or, indeed, other disease among caisson-laborers. But, unfortunately, many improper subjects are permitted to enter into this branch of labor, only to soon be discharged with impaired health, and often irremediable ear disease. The importance of this subject, the writer believes, will justify the introduction here of several illustrative cases from among others which came under his observation :

One individual, aged thirty, states that on several occasions after descending the shaft and going into the lock he had attempted to remain while the condensed air was forced in, but each time the distress in his ears had prevented him, until finally he forced himself to go to work in the caisson while still enduring much distress. The effect of the great pressure proved most disastrous, for he was afterward laid up for a long time with purulent inflammation of both ears.

Another person, whose case was similar to the fore-

going, states that the distress on submitting to the increased pressure in the lock was so great that he was obliged to scream out from the pain in his ears, demanding repeatedly to be liberated, but the man in charge jeered him and he was forced to go to work. In consequence of the injury occurring to the ears he had been prevented from performing any labor for a long time.

Case I.—Lawrence C——, aged twenty-five, a bricklayer, came to the New York Eye and Ear Infirmary, March 4, 1880. Patient began to work in the air-chamber of the Hudson River Tunnel three days ago. Works eight hours daily. From the start there was, on first coming out of the compressed air, a sensation of "cracking air," or rapid concussions like "bubbles of air exploding" in the ears, but mostly in the right one. While at work he is very deaf, and has tinnitus and vertigo, symptoms which have become worse daily. Examination showed the anterior superior quadrant of the right drumhead to be highly hyperæmic. The left external auditory canal was found to contain a large plug of inspissated wax, the impaction of which from the atmospheric pressure gave rise to the vertigo and tinnitus. His teeth are bad, and he is subject to head catarrh.

Case II.—Patrick C——, thirty one years of age, came to the New York Eye and Ear Infirmary, April 28, 1882, complaining of earache on the left side. Three weeks ago he had begun to work in the caisson of the Hudson River Tunnel, and, on account of the exposure, soon contracted a severe head cold, followed in about four days by acute purulent inflammation of the left ear. It began with severe pain in the ear, which lasted for three days, when a discharge set in, which continues. There is intermittent pain in the right ear. The division of workmen to which he belonged labored for eight hours and then rested for sixteen hours. He has frontal headache, and pain in swallowing.

Examination of ears: Left canal filled with pus. Tenderness over left mastoid process, extending down to its apex. The right drumhead is hyperæmic, and has a dusky look

Hearing: Loud voice only in the left ear; ordinary voice in the right ear.

The patient's throat gives evidence of long-standing inflammation, the mucous membrane being thickened and vascular. The tonsils are enlarged and the teeth are very defective.

Case III.—Richard F——, thirty-eight years of age, came to the infirmary, October 30, 1882. Never had any aural disease before working in the caisson of the Hudson River Tunnel, when his ears began to be "blocked up" in passing through the lock, and yesterday morning, when arising from bed, the left ear was painful and felt "blocked." The entire head soon ached, the pains extending down the back. In a short time pain and pressure were experienced in the right ear. On reporting at the works their physician gave him cotton saturated with some fluid to use in his ears, but the pains continued to get worse. Patient worked for four hours, and then rested for nine hours, while employed.

Examination shows the left drumhead to be very hyperæmic, the posterior superior quadrant bulging, more highly congested in one spot, which seems on the point of giving way. The right drumhead is very hyperæmic at upper border and down the malleus plexus. He has decided nasal catarrh, and the mucous membrane of the throat is very vascular and thickened. Hears loud voice only in either ear. Is autophonous in the right ear.

Case IV.—John D——, aged twenty-three, came to the New York Eye and Ear Infirmary, January 29, 1883. States that after working in Hudson River Tunnel for six months his right ear began to trouble him and he had to stop working; it has been discharging for three months. The left ear began to discharge also about a month ago —two months after leaving the tunnel-work.

The discharge in right ear began with otalgia; the left ear has not pained. The tinnitus is very distressing, but intermits. On beginning work the right ear got "blocked" on going into the "lock," and felt "dumb" for a month afterward. In fact, both of his ears often got "blocked," but by blowing his nose, or holding it over steam, the sensation of being stopped up in his ears passed off. He worked in water much of the time, and was much exposed. Confesses to syphilis and intemperance. Examination shows that a perforation exists in anterior superior quadrant of left ear. Canal of right ear narrowed to a slit-like passage, so that drumhead cannot be seen; both canals contain purulent matter. He has very decided nasal catarrh.

Case V.—Michael McC——, aged twenty-six, came to the infirmary, April 12, 1887. Was never deaf before being employed on the Harlem River bridge, connecting Fordam Heights and Washington Heights. He entered the caisson under Harlem River a month ago, and remained at work one "shift" of eight hours only. The pressure was considerable, but the exact amount was not known. He states that soon after going into the lock, with two other laborers, air began to be forced in. He began to feel very uncomfortable; thought his head would "blow off;" his eyes seemed to "pop out," and his ears "cracked." The "boss" told him to hold the nose, close his mouth, and not to breathe. He tried to follow these directions for a couple of minutes, and on taking his hand from the nose it bled. He then shouted to be let out, but the men in the lock said he would soon get used to it, that the first time was the most severe. But the distress continued, and while thus holding the nose and shouting out for relief some thirteen minutes, he was let into the caisson under the river, where he worked for eight hours, though very dizzy and weak in the back. On coming out of the caisson he was very deaf—felt as though he could not speak. He speaks very loud, for fear others will not hear. These symptoms remain, and he has "cracking" in ears on swallowing. Has had pains for two days about the outer canthus of right eye.

Hearing: Loud voice only in right ear at twenty feet; left ear low voice, if plain.

The drumheads are dry, lustreless-looking, and blackened greatly with dust, the atmosphere of the caisson being full of gunpowder smoke. The short process, and the handles of the malleus on both sides look bleached, and they stand out in strong relief from the blackened membranes. The dermic layer of the right drumhead is blistered off in places, especially behind the short process. There are new blebs on anterior segment, and on the flaccid membrane posteriorly.

Patient had long been a hard drinker, and for a week before working in the caisson had had a severe head cold. Ever since the injury he has been "spreeing," and the head catarrh has not abated. The teeth are pretty bad, and he has been subject to nasal catarrh for a long time.

The cause of aural trouble among caissonists is evident from a study of the foregoing cases, when the disturbances produced by high air-pressure on the organ of hearing are considered: Thus, the usual intra-tympanal air-supply having been cut off by closure of the guttural mouth of the Eustachian tube (as from head colds due to exposure, or naso-pharangeal catarrh, or, perhaps, from condensation of pharyngeal air), it is found that the effect of great aerial pressure upon the outer surface of the drumhead is to force it inward. This causes undue tension of the transmitting mechanism, as well as congestion or inflammation of the drum. As the air of the drum decreases by absorption, or escapes into the Eustachian tube in consequence of unusual outward pressure, retraction of the drumhead, of course, gives rise to pain, deafness, tinnitus, vertigo, and other distressing symptoms in the ears and head. Where there is a collection of wax in the external auditory canal it is extremely liable to become softened in such a humid

atmosphere, especially if perspiration be free, and when loosened in this manner the plug becomes, as in one of the above cases, impacted against the drumhead, causing great discomfort. Through carelessness in charging the lock with condensed air, and the neglect of its inmates during the process to maintain tympanal air-renewal (by making frequent efforts to inflate the drum when the nose is held closed, by blowing air from the lungs up into the head while the mouth is closed), much aural trouble is likely to be experienced by anyone exposed, though having sound ears, for during the loss of equilibrium the strain upon the parts gives rise to more or less hyperæmia. Rupture of the drumhead is said to be possible under these circumstances, but such a result must be exceptional unless condensation is very sudden.

On going out from the lock into air of ordinary tension compressed air may remain confined in the drum, and on expansion the drumhead is liable to be forced outwardly. Such being the fact, it behooves persons, in passing out of a caisson-lock where high pressure is maintained, to exercise care as on going in. But where great tension —from forty to sixty pounds—is required, as in tunnel-work, it seems probable that unpleasant effects on the ear can scarcely be avoided, and the greater number who have pre-existing aural trouble will be liable to soon become more or less incapacitated. Men seeking employment in this work, as in any, would often conceal their aural or other physical defects, as well as fail to report any disease incident to the exposure of their unhealthful occupation, and unless a competent medical examination be made of every man before being employed, and at frequent intervals afterward, great injustice may be done to the laborer himself; and, moreover, deaf persons are incompetent in any capacity where their own and others' safety may depend on hearing what is said to them in emergencies. Defective persons, such as have been reported above, are manifestly unfit to be employed in work under highly compressed air.

12 West Thirty-fifth Street.

Clinical Department.

DEATH FROM HYDRONEPHROSIS OF A PARTURIENT WOMAN.

By HELEN W. BISSELL, M.D.,

RESIDENT PHYSICIAN, NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN, BOSTON, MASS.

M. M——, a primipara, thirty years of age, was admitted to the Maternity at 4.40 A.M., August 21, 1887. She appeared in fairly good condition, and walked without assistance. She was then having pains every five minutes, and stated that they began at 2 A.M. The cervix was found to be obliterated, the os dilated 3 ctm., the head low down, fixed, and apparently large and incompressible. The urine, of which the woman passed 240 c.ctm. after entrance, showed albumen present to the extent of two and a half per cent.; specific gravity 1.008; no casts. She gave no history which would lead to the suspicion of renal disease; there was no œdema of the ankles or face.

The external measurements of the pelvis were slightly below the normal, being as follows: External conjugate, 18 ctm.; between anterior superior spines, 24.5 ctm.; greatest distance between the crests of the ilia, 27 ctm.

The head advanced slowly, and with each contraction of the uterus a mass of hemorrhoids was protruded from the anus, equal in size to a large orange, and simulating extensive prolapsus of the rectum. At 7 A.M. the os was dilated, membranes ruptured, the pains were hard and frequent, and the patient was apparently in good condition, with the exception of the hemorrhoids, which gave her great pain. At 8.45 her pulse became suddenly weak and rapid; a stimulant was administered and repeated from time to time without effect, her pulse remaining at 126. At nine o'clock a little mucus in the trachea troubled her during each pain, which in a few moments became more marked; she began to suffer from dyspnœa, and coarse and fine râles could be heard throughout the chest. At each contraction of the uterus the dyspnœa was so extreme that the patient became cyanosed and gasped for breath.

At this juncture forceps were applied, of course without the administration of ether; but as a great amount of force was found necessary, and with each traction of the forceps the pulse became more feeble and running, the œdema greatly increased, and death seemed imminent, their use was for the time being suspended. A hypodermic injection of morph. sulph. (.075) and atrop. sulph. (.0005) was given, which alleviated the symptoms for a short time. After this the patient grew steadily weaker, the respirations were more hurried and shallow, the finger-ends and lips became livid, and a large amount of frothy mucus and blood was expectorated. Death took place at 10.25 A.M. Forceps were immediately applied and a dead child, weighing nine pounds, was delivered. The fetal heart had not been heard for an hour and a half previous to the mother's death, and she stated when she came in that she had felt no movements for three days. Slight twitchings of the hands at the last were the only convulsive movements.

A post-mortem examination showed the upper two-thirds of the left kidney to be represented by a sac the size of a peach, the ureter connected with this being 15 ctm. long, dilated to the size of a broomstick, and containing a cloudy fluid. The lower third of this kidney contained a small amount of green substance, in which the distinction between the cortex and pyramids could be made out. The pelvis was much enlarged, and there was a separate ureter extended from this to the bladder, dilated through most of its course, and constricted 3 ctm. above the bladder. The right kidney was one-third larger than the left, and was dark in color, the capsule being detached with ease. On section the usual relation of cortex and pyramids was found, the surfaces presenting a uniform dark-red appearance; the distinctions between the tubular regions were lost. The pelvis was dilated; and the ureter also, as far as the brim of the pelvis, was dilated to the size of the little finger and distended with fluid, but below the brim it was of normal size. The floor of the bladder was somewhat thickened, and there was a diverticulum the size of an English walnut in the neighborhood of the trigonum. There was 180 c.ctm. of urine in the bladder. The urethra was of normal size throughout. The uterus and ovaries were in a normal condition. The pleural surfaces were adherent in circumscribed spots on both sides. Both lungs were œdematous, with density somewhat increased.

Examination of the brain showed an excess of blood in the pia; the gray matter of the cortex, of the hemispheres, and of the cerebellum was of a slightly purplish hue; puncta crenata were rather large.

A CASE OF POISONING BY CAMPHOR, WITH REMARKS.

By A. BROTHERS, M.D.,

NEW YORK.

On October 1, 1887, I was called to see a man, twenty-six years old, who, I was told, had swallowed camphorated oil by mistake. Desiring to have a movement from his bowels he had sent a little girl for five cents' worth of castor-oil, and the druggist, misunderstanding what she wanted, gave her, instead, camphorated oil, taking the precaution of putting on the glass the proper printed label. At noon the patient, not noticing the label, poured some whiskey into the glass to disguise the taste of the supposed castor-oil, and with one gulp swallowed the entire contents. He did not discover his mistake for several hours. In the course of an hour he felt uncomfortable. He soon began to have an intense

headache with aching in the limbs. He suffered chills, nausea, and general weakness. There was a strong odor of camphor perceptible in his breath. The headache steadily increased in severity and almost drove him crazy. At four o'clock he passed a small quantity of urine which smelt of camphor. Shortly after five he took a walk for about an hour. On returning he sat down to supper, and while partaking of a hearty meal he suddenly grew deathly pale and passed off in a fit. The convulsion was general, but without frothing at the mouth or biting of the tongue. He soon passed into an unconscious state, from which he was gradually emerging on my arrival, about seven o'clock. I found him sitting in a chair in a half-dazed condition. He answered questions intelligently, but did not like to be bothered. The pulse was full, strong, and eighty per minute. The face was somewhat flushed. He complained of no pain in the mouth, throat, or stomach. There were no erotic desires. His breath smelt of camphor. The pupils seemed to be normal. I ordered him a dose of calomel (twenty grains) and bromide of potassium (thirty grains) every four hours. After the first dose of medicine he vomited his undigested supper, strongly impregnated with camphor. He spent a very restless night, but next morning was well enough to leave the house. The urine now began to be passed freely, and convalescence was established. After consulting the druggist I estimate that the amount of camphor taken in this case was about one hundred and fifty grains. Considering that most of this quantity must have been absorbed during the eight hours that it remained in the stomach, this case deserves to be ranked among the more interesting ones of this variety of poisoning.

In a fairly extensive search through the literature of the subject, I only met with thirty published cases of camphor-poisoning. The smallest quantity said to have produced toxic symptoms in the adult is seven drops of "Homœopathic Solution of Camphor" (one ounce of camphor to one and a quarter ounce of spirit), representing six or seven grains of camphor. This dose was followed, in a young lady, by extreme drowsiness and weakness of the pulse.[1] Albutt gave an Alpine guide twenty drops of this solution for a diarrhœa, but the man became so sick that he was unable to proceed in the ascent.[2] Similar cases, in which alarming symptoms have followed after comparatively small quantities of camphor, are reported by Johnson,[3] Ryan,[4] Hall,[5] and Klingelhoeffer.[6]

On the other hand, very large doses of camphor have been taken, giving rise to alarming symptoms for a certain length of time, but ultimately terminating in recovery. To this class belongs my case, in which probably one hundred and fifty grains were taken in fluid form, and remained in the system for eight hours without killing the patient. The largest single dose of camphor taken without fatal effect is two hundred grains.[7] A woman, aged forty, took this quantity of camphor in alcoholic solution, and developed convulsions followed by coma. On the following day she was convalescent. Another lady, aged twenty-five, swallowed an ounce of camphorated oil, and passed into a condition of wild delirium alternating with unconsciousness. Improvement set in four hours later.[8] Cases of this nature have been reported by Cowen,[9] Pollak,[10] Eickhorn,[11] Aran,[12] East,[13] Lederer,[14] Appleby,[15] Johnson,[16] and several others.[17]

[17] Phil. Med. Times, 1879; Med. Times and Gaz., 1858: Med. Age, 1883: Nat. Dispensatory, 1884: Taylor: On Poisons.

There are five fatal cases of poisoning by camphor on record. Two cases are cited by Taylor ("A Treatise on Poisons") in which two infants, respectively fifteen and eighteen months of age, died within twenty-four hours. The third case occurred in a boy, two years of age, who developed convulsions after swallowing about fifteen grains of camphor, and died in four hours.[1] In the fourth case, a child of two years and eight months of age passed into convulsions after taking about a half-drachm of camphor, and died eighteen hours later.[2] The fifth case was that of a woman who took one hundred and eighty-four grains to bring on an abortion. This she succeeded in doing, after suffering the usual symptoms of camphor-poisoning. It is doubtful whether she died as a result of the abortion or of the camphor.[3]

In toxic doses camphor gives rise to a great variety of symptoms, but by far the most frequent and characteristic are those involving the nervous system. Convulsions rank among the most prominent of these. They may be severe or mild, general or local. They may come on very early or very late after taking the poison. There may be a single convulsion terminating in recovery or death, or the attacks may be repeated during many hours. The convulsions are most frequently followed by a condition of unconsciousness, from which, however, the patients can usually be roused. In some cases this amounts to a mere state of drowsiness. It may be entirely absent even after the largest quantities have been taken. In most of the cases headache is one of the earliest symptoms. It may be of different types and of different grades of severity. With it there usually exist dizziness, noises in the ears, and dimness of vision. The cerebral faculties become excited at times, so that the patients are restless, or hilarious, or even wildly delirious. This excitement is usually followed by profound sleep or unconsciousness. Among the nervous symptoms occurring less frequently may be mentioned pain in the back of the neck, followed by rigidity, pain along the entire spine, abnormal sensations (numbness, crawling, and tingling), partial paralysis of an extremity, and absence of cutaneous reflexes. The pupils are most often dilated.

Digestive disturbances occur with frequency. These embrace loss of appetite, nausea, eructations, and vomiting of matter impregnated with camphor. Flatulence, pain in the epigastrium, and cold sensations in the tongue are among the more unusual symptoms.

On the heart, the action of camphor in toxic doses seems to vary. In some cases the pulse ranges between 48 and 100, being full and strong; in others it is rapid, feeble, and irregular.

In nearly all of the cases the odor of camphor is easily perceptible in the breath. In some cases the breathing is imperceptible, in others it is labored and stertorous.

The surface temperature may be subnormal or elevated. The internal temperature is usually normal, but may reach as high as 105° F. The secretion of urine is usually diminished during the first twelve hours, and, when passed, may smell strongly of camphor. Erotic desires are usually absent. Prostration is always more or less marked. The face may be pale or flushed. The skin may be moist or dry.

I have thus briefly reviewed the different symptoms which may arise from camphor-poisoning. These symptoms show no direct relation to the quantity of poison taken, for some of the most alarming cases have followed the taking of comparatively small quantities. The most diagnostic signs are the occurrence of convulsions followed by semi-unconsciousness, and the odor of camphor in the breath. The prognosis varies with the age of the patient, being worse in infants and old people than in robust adults and older children. In four to eight hours after taking the poison most of those who recover are

[3] H. C. Wood: Therap Mat. Med. and Toxicology.

out of danger, and after twenty-four hours the majority of the cases are perfectly recovered. The proper treatment consists in removing as much of the poison as possible by emetics. The convulsions must be controlled by bromide of potassium or opium. Other symptoms must be treated as they arise.

MAGNESIUM SULPHATE IN POISONING WITH CARBOLIC ACID.

By GEORGE W. NEWTON, M.D.,

CHICAGO, ILL.

"Mrs. M——, aged thirty-eight, was confined Wednesday, August 31, 1887. The following Sunday her husband gave her a tablespoonful of ninety-five per cent. carbolic acid, intending to give castor-oil, which had been ordered the day previous. She took it at one swallow, wishing to avoid the taste of the oil; instantly she knew there was a mistake. The husband ran to my office, which was three blocks away. I wrote a prescription for sulphate of magnesia, and went to the house as quickly as possible. Probably twenty minutes had elapsed from the time she took the acid until I saw her. Then she was totally unconscious, pulse extremely irregular, first rapid and bounding, then slow and feeble; the body bathed in a cold, clammy perspiration, hands and feet cold. There was constant jactitation. Unconsciousness came on in less than three minutes after the acid was taken.

"As soon as the mistake was discovered the monthly nurse gave her two or three tablespoonfuls of lard, and before I arrived they had given her nearly one ounce of sulphate of magnesia. Her condition seemed so hopeless that medicine was administered more to satisfy the family than with the expectation of it doing good. She swallowed with difficulty, the attempt causing spasm of the muscles of deglutition. A hypodermic injection of whiskey steadied the heart, and in three-quarters of an hour from the time I arrived consciousness began to return; then we gave the sulphate very freely, nearly three ounces being used, and in addition I gave her the whites of three eggs. In another hour her condition had improved so much that I left her for an hour; during that time she vomited freely. Ice was then applied to her throat, and she was allowed to swallow small pieces to quench her insatiable thirst. Consciousness did not fully return until two o'clock in the afternoon. Pulse at 2 P.M., 90, but regular and not very weak. From this time until her recovery there were no untoward symptoms.

"Tuesday morning her temperature reached 100° Fahr.; it never went higher. For nearly one week she complained of soreness in her throat and experienced considerable pain in swallowing. Only one day did she complain of pain over her stomach. Ice was kept upon the throat continually for five days, and small doses of opium were given to allay the pain in the throat. Bismuth, lime-water, and small bits of ice were given for the gastritis, also flaxseed tea. Nourishment was given entirely by enema for three days, then she was allowed small quantities of partially peptonized milk. At the end of seven days the enemata were stopped. At the end of four weeks her recovery was complete. I feel convinced the sulphate of magnesia saved her life. Although she took nearly three ounces her bowels moved only once. The urine remained normal in color. A curious fact about the case is that there was not more soreness complained of in the region of the stomach."

The doctor is a generous man,
But people cheat him when they can;
They have their health restored on trust,
And pay him something when they must,
And swear no bill is bigger than
The doctor's.—*National Druggist.*

Progress of Medical Science.

The Innervation of the Bladder.—From a study of this subject Dr. Born has reached the following conclusions: 1. Neither by direct nor indirect faradization and galvanization can we cause contractions of the bladder. 2. The existence of a vesico-spinal centre in the lumbar cord is not proved. It is unnecessary in man, since the internal sphincter vesicæ suffices. That name may therefore be given to the detrusor centre in the lumbar cord. 3. All acute spinal lesions cause retention. Those at the level of the lumbar cord by direct paralysis of the bladder, others by lowering the tone, during which the bladder becomes so distended by urine that it loses its contractile power. 4. The assumption of reflex controlling fibres, which in micturition control the normal reflex of the sphincter urethræ (and lesion of which causes the so-called spastic retention of urine), is unfounded.—*Deutsche Zeitschrift für Chirurgie.*

The Employment of Saccharin.—This substance is now prominently before the profession, and the following memoranda, taken from the *British Medical Journal*, October 15, 1887, contain information that it may be well to remember: "Saccharin forms a white crystalline powder, which fuses at a temperature of 392° F., when it undergoes partial decomposition, giving off a characteristic odor. It is but slightly soluble in cold water, somewhat more so in warm water, its solubility being, however, greatly increased by the presence of alkalies or their carbonates. Alcohol also furnishes a good solvent for saccharin, particularly eighty per cent. solutions, and it is likewise freely soluble in warm glycerine. Its most characteristic property is certainly its sweetening power, possessing nearly three hundred times that of cane-sugar, for while a solution of cane-sugar loses its sweetness when diluted to 1 in 250, a sweet taste is still perceptible in a watery solution of saccharin containing 1 in 70,000. As sugar is a carbo-hydrate, its solutions are liable to undergo fermentation; but as saccharin is an aromatic derivative, it is not liable to undergo this decomposition, and hence it may be freely employed without the fear of destructive fermentation occurring. But, besides this, as saccharin possesses considerable antiseptic powers, its use in medicine may often be attended with advantage—as, for example, in cases of alkaline fermentation of urine, upon which it has been shown to exert a strongly retarding influence. Stutzer, Aducco, and Mosso, from their experiments with this body, agree in the belief that it is innocent, so far as the organism is concerned; and Stutzer's experiments further show that its presence has no retarding influence on the digestion of either proteids or hydrocarbons. However administered, saccharin soon finds its way into the urine unaltered, this fluid not being altered thereby. And, while producing no injurious effect on the system, it is found to agree both with invalids and healthy individuals, and no anxiety as to its effect upon the health need be felt, even when taken for lengthened periods. As much as thirty to eighty grains have been administered daily without producing any injurious effect, even upon the appetite. Saccharin may therefore be said to be neither a food nor a poison; but from its peculiar properties it may often be employed therapeutically with advantage. Thus it may with benefit wholly or partially replace sugar in the diet where the latter is contraindicated, as in diabetes, general obesity, torpid liver, marked gouty diathesis, chronic glandular diseases of children, and in certain senile affections in which various cystic and genito-urinary disorders occur. From half a grain to a grain and a half of saccharin will sweeten a cup of tea or coffee. Small saccharin tablets, indeed, have been prepared for this purpose, and these are now being supplied, it is said, to the German army; for in a very small bottle of scarcely appreciable weight a soldier can carry

enough saccharin for a week's supply. There is a wide field for the application of saccharin to the production of sweetmeats and preserves, and in disguising the taste of bitter and nauseous preparations, as well as in preserving the properties of others. But it must always be carefully borne in mind that saccharin is to be regarded as a condiment, and not as a food like sugar, and can therefore replace sugar only in exceptional cases."

Stricture of Urethra in a newly Born Child.—Dr. Macan, of Dublin, showed before the Academy of Medicine of Ireland the parts removed from a child which was born at full term but died soon after birth. There was congenital stricture of the urethra at the external orifice, great dilatation and hypertrophy of the bladder, and cystic degeneration of the kidneys. Dr. Macan pointed out that the condition of the bladder and kidneys was due to the stricture of the urethra, and remarked that "the fœtus must have spent a good deal of its time in making water in order to produce such hypertrophy (of the bladder) as was seen in the specimen." The child had other malformations besides the contracted urethral orifice, viz., spina bifida and imperforate anus.—*Dublin Journal of Medical Science.*

The Utility of Nux Vomica.—A French physician claims to have employed nux vomica successfully in the nervous movements of pregnancy, gastralgia, dyspepsia, hypochondriasis, nervous palpitations of the heart, nervous and periodic cough, asthma, and, finally, in albuminuria. He thinks this remedy acts either on the pneumogastric, or on the great sympathetic, or on the spinal cord. He records the case of a lady affected with a severe cough, recurring every evening and lasting throughout the night, who was cured in two days by the use of nux vomica. Another patient was affected every evening with violent cough accompanied by catarrhal expectoration, and was also cured in two days by the alcoholic extract of nux vomica. Cough may also be allayed by this means, whether it be caused by bronchitis, by pneumonia, by pulmonary phthisis, or by emphysema. It proves a useful remedy also in cases of cardiac pulsations, and in irregular or too frequent action of the heart.—*Journal de Médecine.*

Insolubility of Antipyrin.—Dr. Carl Proegler writes that he was astonished to read in the report of the proceedings of the Neurological Society that antipyrin is insoluble, for he has always given it with dilute nitromuriatic acid, and found it perfectly soluble. He has learned by experience that the drug is especially valuable in headaches of malarial origin. In these cases he gives it in five grain doses every hour, until three or four doses have been taken.

The Contagium of Scarlet Fever.—Some interesting researches have lately been conducted in Edinburgh, by Dr. Edington, the object being to discover the "germ" of scarlet fever. Dr. Edington found a particular bacillus in the blood early in the disease, and in the desquamating epithelium at a later date. This organism was found capable of giving rise in animals to a disease resembling scarlet fever.—*Glasgow Medical Journal.*

An Approaching Scarcity of Physicians in France.—It is said that the number of physicians in France is steadily decreasing, while the population of the country is on the increase. In 1883, 662 diplomas were granted by the medical schools of France; in 1884 there were 590; in 1885 the number was 575; and in 1886 there were only 546. In the Parisian schools alone, during the same period, the number of diplomas granted has declined from 465 to 336. The deficiency is felt chiefly in the country districts, the large centres of population being still well supplied.

The Dread of Colors.—R. Hilbert (*Centralbl. f. prakt. Augenheilk.*) holds that cases of chromophobia, though they have been rarely recorded as such, are not very uncommon, and that they deserve attention as examples of perversion of the color-sense. In the cases to which he refers, pathological changes in the visual organs are not discoverable, and the morbid sensation does not occur as a subjective phenomenon independent of objective colors; in the persons affected an objective color produces an excessive and disagreeable effect. The first recorded case is by Woinow; the subject of it was a color-blind person specially affected by red. Hasner published three cases, presenting dread of white, dread of red, and dread of blue respectively. Schröter followed with two cases: dread of blue in a patient with atrophy of the optic nerves, and dread of red in an otherwise healthy man. Mayerhausen described two more cases of dread of red, in nervous and highly excitable persons. To these eight cases Hilbert now adds another. A student, twenty-six years of age, came to consult him on account of a chronic follicular conjunctivitis. A sheet of carmine red paper happened to lie upon the table. The patient started when he saw this, closed his eyes, and begged that it might be removed. He stated that from his earliest childhood the sight of red objects, clothes, and such like, had distressed and excited him. Other colors, shining surfaces, and bright light caused him no inconvenience. The patient was a small, weakly man, of restless and excitable temperament, and somewhat hypochondriacal. He had a slight myopia, with normal acuteness of vision; the media and fundus were healthy in both eyes. In the cases hitherto recorded, including Hilbert's, red was the color dreaded in six cases, blue in two, and white in one; whether other colors ever have a similar effect, there is no evidence to show. In all the cases but two the eyes themselves appeared to be healthy, but in every case there was a certain over-excitability and nervousness of temperament, and this, no doubt, underlies the special liability to excessive impression in the visual centres. The author regards the symptom as a central one, and not as a sign of disturbance in the retina.—*Dublin Journal of Medical Sciences.*

Illegitimate Practice in Germany.—Before the year 1868 the Prussian law prohibited irregular practice by unqualified men. In that year, however, the law was repealed under the feeling that it was impossible to put down such practice, and that there was a sort of unfairness in having a law of such a nature that a wholesale breach of it was inevitable. Since then efforts have been repeatedly made by the profession for a return to the former condition, to prohibition, but even in the profession itself a wide difference of opinion prevails as to the advisability of such a step. For the purpose of arriving at some kind of concerted action a joint meeting of members of the Berlin Medical Society and the Central Committee of the eight Medical District Unions was called for the 8th inst. Two speakers were selected, one on each side, to discuss the subject. Professor Mendel, as the advocate of those who were opposed to a renewal of the law, opened the discussion in a lengthened address. The champion of the opposing party was Dr. Becker, President of the Central Committee of the Berlin Medical Unions. It is scarcely necessary to follow the discussion; suffice it to say that at the close the following resolution was proposed and put to the vote: "That the renewal of the prohibition of irregular medical practice, by the introduction of a decision to that effect in the German Strafgesetzbuch, is necessary in the interests of the common weal." The resolution was passed by 168 votes against 164, not a very brilliant triumph for the coercionists, or, as Professor Virchow, who is opposed to a renewal of the law, put it, "Das ist nur ein Pyrrhus Sieg!" It is scarcely likely that any action will be taken by the Government when even professional opinion is so evenly divided on the subject.—*Medical Press.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 10, 1887.

THE PATHOLOGY OF OLD AGE.

A WORK of unusual interest in many respects is one recently published by Dr. Émile Demange, of Paris, upon the pathological anatomy and clinical history of old age. Dr. Demange has had unusual opportunities for studying senility in its various phases in the Hospital for the Aged, at Nancy. His pathological observations include more than five hundred autopsies.

Like most popular French scientists, Dr. Demange delights in reducing things to a formula. In the present case the dominating idea of the book is that the changes of senility are due to disease of the blood-vessels, and that the arteries make us old. In his five hundred cases there was always vascular disease, at least in the smaller vessels. Its characters were a proliferation of the endothelium, thickening of the middle muscular coat, and proliferation of the external coat—in fine, a "fibrous endo-peri-arteritis," tending to narrow and close the vessel's lumen.

The sclerosis thus produced tends to radiate from the blood-vessels, and causes wasting of the parenchyma. Such is the view of Demange.

Charcot, on the other hand, attributes the wasting to insufficient nutrition, through partial closure of the vessels. In the larger vessels atheroma takes place through the obliteration of vasa vasorum by arteritis. In the heart there is first an endo-peri-arteritis of the coronary arteries, consequent sclerosis of the cardiac muscle, atheroma of the endocardium and valves, and finally hypertrophy and dilatation, due to the peripheral obliteration. This compensatory hypertrophy of the senile heart has been described by Charcot and others. The signs of this senile hypertrophy are not always especially characteristic; indeed, in old people the heart is one of the best of the organs. Owing to the atrophied and emphysematous lungs, and to the more rigid thorax, the blood of the aged is poorly oxidized, and has more of a venous character than in earlier life; it coagulates more easily; the corpuscles and the hæmoglobin diminish, while cholesterin and urea increase. The blood is more toxic in quality therefore.

The central temperature of the aged, contrary to general belief, is not much different from that of early life. The digestive organs are affected in varying degrees with atrophic change. The mucous membrane of the stomach and intestines is white, thin, and glossy, and its arteries atheromatous. The liver is small and sclerotic, while the kidney can hardly be distinguished by the naked eye from the cirrhotic or gouty kidney.

Similar atrophic and fibrous changes affect the system throughout. They are all due primarily, according to Demange, to the vascular disease. This lessens the nutrition, the cells atrophy, sclerosis follows, or, still more often, the sclerosis radiates from the vessels and encroaches on the parenchyma, compressing the cells and causing their atrophy.

To the question, What causes the arterial disease? Demange answers that it is the irritant effect of an excess of products of disassimilation circulating in the blood, a vice of metabolism. But as this excess of irritants comes from the tissue-cells, we find that senility, after all, is due to that loss of balance between assimilation and disassimilation which is part of the great biological law of life and growth. We must grow old; it is registered in the protoplasm of the cell from the moment that life was imparted to it.

CHRONIC RELAPSING FEVER.

IN a paper read before the Medical Society of Göttingen, July 7, 1887, Professor Ebstein reported the history of a rather remarkable case, which was believed to be almost unique in medical annals. The patient was a mechanic, nineteen years of age, of rather delicate constitution, but giving no history of any hereditary taint. In the early summer of 1886 the man began to suffer from periodical attacks of headache, lassitude, anorexia, and abdominal pain. No temperature-record was taken until the month of September, when it was found that fever coexisted with the other periodical symptoms. The temperature during the paroxysms rose to 104° F., and sometimes even to 106° F. During the apyretic periods the temperature was often subnormal, falling sometimes as low as 96° F. There was no abrupt rise or fall, but the temperature passed gradually from the maximum to the minimum, and back again, in an even curve. Nine of the paroxysms had occurred between the middle of November, 1886, and the date of the report. The spleen was always enlarged during the attacks, and it was also tender on pressure. The only alarming symptom was weakness of the heart, which was so extreme as at times to seriously threaten the life of the patient. The pulse was rapid, frequently reaching 136 to 140 beats in the minute. The blood was examined from time to time, but no microorganisms were ever found. No cause for the disease could be discovered. The patient lived in good hygienic surroundings, and removal to another neighborhood failed to break up the recurrent paroxysms.

A case very similar to this was reported, a few years ago, by Dr. Pel, of Amsterdam. The patient, a man twenty-five years of age, had four relapses, and died in the fourth from heart-failure. The autopsy revealed a marked hyperplasia of the spleen and of the retro-peritoneal, mesenteric, and bronchial glands.

Ebstein's case is peculiar, as the course of the fever corresponds to that of no other known disease. The possibility of a malarial causation would seem to be excluded by the fact that a persistent use of quinine and arsenic exerted no influence upon the temperature-curve. In true relapsing fever, as many as five relapses have

been observed. But that this is not a case of unusually prolonged relapsing fever is evident from the fact that examination of the blood failed to reveal the presence of Obermeier's spirilla, and the gradual defervescence also serves to distinguish it from true recurrent fever. The disease has not, we believe, except in these two instances, been hitherto described. Ebstein has therefore a right, we suppose, to give it a name, but it is a pity that he has not chosen more happily. The term of chronic relapsing fever is evidently faulty, for, excepting the recurrent paroxysms, the disease appears to differ widely from the acute affection known under that name.

THE THERMOTAXIC HEAT-CENTRES.

European writers seem averse to acknowledging the fact that some of the best experimental work in connection with the subject of fever has been done in this country by Wood, Ott, and their pupils and assistants. In particular, the credit of localizing the heat-centres in the nervous system is due to Dr. Ott, though Sachs and Aronsohn independently made similar discoveries later. Girard and Baginsky have also made original observations and experiments regarding this subject, confirming the view that there are heat-centres in the brain and cord. The facts regarding the cerebral heat-centres are summarized in a paper by Drs. Ott and Carter in the *Therapeutic Gazette* for September, 1887.

The brain-cortex (of the rabbit) contains, according to the authors referred to, no heat-centres, their irritation or destruction causing only temporary variations in bodily temperature. In the deeper structures of the brain are four localities the irritation of which causes a rise of temperature, which continues for several days, and is not due to vaso-motor or inflammatory changes These centres may also depress temperature under certain kinds of stimulation. It is believed, therefore, that they act both as exciting and inhibitory centres according to the form of stimulus they receive, and the general name of thermotaxic or heat-regulating centres may be given them.

The location of these centres is as follows: (1) In front of and beneath the corpus striatum. Puncture here causes a quick rise and slow decline of temperature. (2) The parts on the inner side of the nodus cursorius. Irritation here causes a gradual rise of temperature. (3) The parts about the anterior inner end of the optic thalamus. Punctures in this region give a very high fever, the temperature rising frequently to 109° F. The thalamic heat-centre is apparently the most sensitive of all. (4) The parts between the optic thalamus and the corpus striatum near the median line, or near what is called Schiff's crying centre. Punctures here are followed in male rabbits by a peculiar cry, and in both sexes by a rapid rise of temperature, which slowly descends. The temperature-changes last from two to four days.

MORPHINOMANIA AND MENSTRUATION.

Opium is a remedy of the greatest value in many affections of the female generative organs, and is perhaps employed as often as any other single drug in these disorders. This is, however, almost as often a curse as it is a blessing, and there is many a woman whose joy over her relief from uterine disease has been turned into bitterness at the discovery that she has become a slave to morphine. However, there are certain forms of incurable uterine disease in which opium may be given with an unsparing hand, and in which naught but good can result from its free administration.

In a paper read before the Medical Society of Paris, April 23, 1887, Dr. Lutaud referred to the peculiar property which he had observed in morphine, when taken in large doses, of arresting the performance of the menstrual function. He cited a number of cases which had come under his observation, in which this function was in abeyance. The patients were addicted to the use of morphine in large doses, and applied to him for the cure of amenorrhœa. In some he was unable to cure the morphine addiction, and in these the menses did not return. In others the habit was broken up, and the menstrual function was restored. Some of the latter afterward resumed the use of morphine, and then the menses again ceased.

An analogous action of the drug, in arresting uterine hemorrhage, was observed in disease, especially in cancer. In a number of cases of this nature he found the constant use of large doses of morphine to be of the greatest utility. This property of the drug would seem to fit it to fulfil a special indication in those cases of incurable uterine disease which are aggravated by profuse menstruation. The author, indeed, goes so far as to advise the production of a true morphine addiction in cases of cancer or incurable uterine fibroids, although he deplores the reckless use of the drug in other less intractable affections of the womb. This would hardly be a safe rule to follow in all cases indiscriminately; yet if morphine can ever be given without fear for indefinite periods, it is precisely in these irremediable and hopeless cases of carcinoma of the uterus.

TRUE AND FALSE RICKETS.

In a recent notice on the use of phosphorus in the treatment of rachitis, in these columns, we referred to the difference of opinion among competent observers as to the value of this therapeutic method. While the weight of testimony seems to be decidedly in favor of the efficacy of phosphorus, there are yet many who have given the drug a faithful trial only to condemn it as utterly worthless. This discrepancy cannot be due wholly to the difference in the modes of exhibition of the remedy, as some have claimed, for in many cases the mode of preparation and the dose given have been identical, yet the results have been far from uniform.

In *Il Raccoglitore Medico* for October 30, 1887, Dr. Eugenio Casali, in an article advocating the employment of phosphorus, offers another explanation of the indifferent results obtained by some observers. There are, he says, two forms of rickets—a true and a false, or, rather, there is often a delay or an arrest of ossification which may simulate very closely actual rachitis. This arrest of ossification occurs in children who have been debilitated by improper food, or by some exhausting disease, such as chronic intestinal catarrh. The most important diagnostic signs of true rickets, as distinguished from simple arrest of ossification, are tenderness on pressure over the enlarged epiphyses and the coexistence of laryngismus stridulus. In false rickets there is, furthermore, a history of some antecedent disease, usually

chronic diarrhœa, which has seriously interfered with the nutritive processes. In true rickets Dr. Casali asserts that phosphorus acts as a veritable specific, bringing about a cure in a very short time; but in the simple arrest of ossification he has never seen it accomplish any good. The results obtained by the use of phosphorus go far, he thinks, to support Kassowitz's theory, that rickets is a disease depending on the presence of a specific micro-organism, for the amount of the drug necessary to effect a cure was wholly insufficient to supply the supposed lack of phosphorus in the osseous tissues. Furthermore, there was a very great increase in the quantity of phosphates in the urine during the time that the remedy was administered, showing that little, if any, of the drug was stored up in the system.

RENAL STONE AND ITS DIAGNOSIS.

Since the operation of nephrectomy was first established by Simon, in 1869, there have been, according to Gross, two hundred and thirty-three cases reported, with a mortality of 44.63 per cent. The records of the later work of surgeons in this line no doubt give better results than are indicated by a consideration of all cases, including those operated upon when the technique was less perfectly understood.

An operation apparently much more brilliant in results than nephrectomy is that of nephro-lithotomy, first performed by Mr. Henry Morris in 1880, for removal of a renal calculus. This has now been done over twenty times, with a mortality of only eight or ten per cent.

It seems, therefore, as if, by the help of modern renal surgery, kidney-stone could now be treated with satisfactory results. In a recent number of the *Practitioner*, Mr. Jordan Lloyd, of Birmingham, calls attention to some views of his own regarding this matter. One trouble, he thinks, in the surgical treatment of renal lithiasis, is that the diagnosis is quite as often made incorrectly as otherwise. In twenty-five instances kidneys have been "explored" for supposed renal calculus without any stone being found. The operators in three cases have not been deterred by the trivial fact of a false diagnosis, but have taken out the kidney just the same. The kidney, like the ovary, has to pay its tribute to the mad frenzy of the modern record-making surgeon.

Mr. Lloyd thinks that fewer mistakes will be made, first, after the knowledge of clinical symptoms is more complete, and second, when present misconceptions of the anatomy of the renal pelvis are corrected.

As to the latter point, he claims to have demonstrated, by casts taken from human kidneys, that the pelvis is an utterly different arrangement to what the text-books would lead us to believe; and that, instead of its being a "funnel-shaped membranous sac," chiefly located in the organ's interior, it really consists of a cluster of branching tubes; so that the procedure of exploring the kidney's interior, by means of a finger introduced into the pelvis through an opening in the kidney-substance, is practicable only in dilated kidneys, and is absolutely impossible when we are examining the interior of the viscus in anything approaching a normal condition. Mr. Lloyd has not yet found a healthy human kidney into the primary pelvic tubes of which he could introduce his index-finger. The precise anatomical arrangement of the ureter and pelvis is stated to be as follows: "The ureter as it approaches the kidney enlarges from its normal calibre—about that of a No. 10 English catheter—until it measures from one-third to half an inch in diameter, and immediately on entering the hilum it breaks up into two, or sometimes three, primary tubular branches, varying in diameter from a No. 10 to a No. 20 English catheter, and measuring from a half to one and a half inch in length. These in turn give off secondary tubes, smaller in size—some less than a line in width—which end in cup-shaped calyces. Sometimes tertiary branches, still smaller in calibre, shoot off from these secondary tubes to end in calyces. With such a conception of the structure of the kidney's interior, many of the occasional difficulties with regard to symptoms, prognosis, and treatment of renal calculus are made more easy to understand."

Mr. Lloyd contributes a method of reducing the number of "missed calculi." It consists essentially in cutting down on the kidney by a lumbar incision. A long tenotome is then thrust through the kidney into the lowest calyx. Through this opening is passed a child's bladder-sound, and the pelvis thoroughly explored.

The leading symptoms of renal stone, as given by the author in question, are as follows:

"Pain of a dull, heavy, dragging character, constantly located in one loin, sometimes shooting down the course of the ureter and along the spermatic cord to the testis, and always increased by exertion, is fairly diagnostic of stone; but, unfortunately for our art, the symptoms of disease are rarely true to type, their manifestations are capricious, and their inconsistencies are manifold.

"Pain may be present in both loins, and it then becomes very perplexing; or it may be referred to other and distant parts, so that the lumbar trouble may be altogether uncomplained of.

"It may be brought on by an injury. Much importance is attached to percussion of the region over the kidneys. The patient should stand upright, and the blow should be a sharp one. When a calculus is present the patient will complain of a stabbing pain, caused by the blow."

THE NEW YORK CANCER HOSPITAL.

The New York Cancer Hospital, which was formally opened this week for the reception of patients, is the only one of its kind in this country, and bids fair, with the means to the end of treating the most dreaded of all diseases, to mark an era in the history of public institutions in this city. Desirably situated, handsomely built, and thoroughly equipped as it is, it gives a reasonable promise of great usefulness. With the objects, not only of affording relief for a large class of sufferers, but of stimulating research and perfecting skill, it certainly lays claim to the heartiest good wishes of every lover of humanity, and the best encouragement to every scientific student of our noble art. It is not fair to assume that because cancer is now, as a rule, incurable, that we may not yet find some remedy as efficacious for its successful treatment, as is bark for intermittents and mercury for syphilis. At least we should be tireless in our endeavors to make such a realization possible. The Cancer Hospital, dedicated to such high purposes, modestly and

earnestly appeals to the profession of this country for aid and encouragement.

The situation of the new hospital, on Eighth Avenue on the block between 105th and 106th Streets, is as pleasant and in every way desirable as any that could be chosen, facing Central Park and commanding a fine view of the northern part of the city; and the building itself would much more readily be taken for an art museum than for a hospital. The architect, C. C. Haight, deserves much credit for designing a beautiful as well as a thoroughly useful structure. The present edifice is to accommodate women only, and an addition for the use of men will be made at the southwest corner.

Besides these, there are private rooms for such patients as have means to pay for them, and also for such as, from the nature of their cases, need to be separated from the others, whether thay have means or not. In fact, though a small sum for board will be charged to all who can pay, patients will be received quite as readily who can pay less than the regular rate, or even nothing at all. The wards and private rooms will accommodate seventy-seven patients in all.

The building is one hundred and eighty feet long on the Eighth Avenue side, eighty feet deep on 106th Street, and four stories in height above the basement. The exterior is of hammered brownstone and red brick. A novel feature is the three huge towers which stand at three of the corners. In these towers are situated the wards for the patients, the object being to obtain as perfect ventilation and as much light as possible.

The interior is almost severe in its simplicity, though very cheerful from the flood of sunlight that pours in through the many windows.

The main floor contains the office of the superintendent, reception-rooms, offices of the medical staff, and a chapel. The walls of this floor are of red and white enamelled brick, and the floor of tiles. The chapel is on the Eighth Avenue front, and opens on a balcony with glass roof, which will be devoted to the use of convalescents.

The main staircase is of bronze, with stone steps. The second and third floors are alike in their arrangements, and contain the wards and private rooms. There are four public wards—two in each tower. Each ward accommodates eleven patients. The remainder of the second and third floors is taken up with private rooms containing one and two patients.

On the top floor are the operating theatre, rooms of the nurses, and the culinary department of the hospital. Connected with the operating theatre is a small room where the anæsthetics are administered.

The laundry, servants' quarters, and autopsy-room are in a separate building.

The building is the gift of John Jacob Astor, and he and Mrs. Elizabeth Hamilton Cullum are distinguished as the founders of the hospital, a title obtained by the gift of $50,000 or more at one time. Mrs. Robert L. Stuart and Mrs. Charles Rogers are patrons by subscription, by the gift of $10,000 or more. Givers of endowed beds in perpetuity, by the gift of $5,000, are John E. Parsons, Joseph W. Drexel, Morris K. Jesup, Mrs. Charles Rogers, William Astor, Mrs. C. P. Huntington, Mrs. John Jacob Astor, and Mrs. Cullum.

The Board of Managers of the new hospital is as follows: President, John E. Parsons; treasurer, Joseph W. Drexel; secretary, Dr. A. Brayton Ball; Mrs. Matthew Clarkson, Mrs. Paul Dahlgren, Mrs. Phœbe Lord Day, Mrs. Howard Townsend, Mrs. William Butler Duncan, George P. Andrews, J. C. Drayton, Dr. J. F. Alexander, Dr. C. Cleveland, Dr. J. B. Hunter, Dr. F. P. Kinnicutt, and Dr. W. T. Bull.

The Medical Staff comprises the following gentlemen:

Consulting Physicians and Surgeons: Drs. Fordyce Barker, Thomas M. Markoe, John T. Metcalfe, T. Gaillard Thomas, T. Addis Emmett, W. H. Draper, George F. Shrady.

Attending Physicians and Surgeons: Drs. James B. Hunter, A. Brayton Ball, Clement Cleveland, Francis P. Kinnicutt, William T. Bull.

Assistant Physicians and Surgeons: Drs. B. Farquhar Curtis, J. S. Hawley, H. C. Coe, W. G. Thompson, Charles Ford, *Superintendent.*

The opening exercises took place on the afternoon of Tuesday, and were attended by a large audience of leading ladies and gentlemen, who afterward inspected the wards and outhouses. The President of the Board, Mr. John E. Parsons, in an opening address, explained the construction and purposes of the hospital, and was followed by Dr. Fordyce Barker, the senior consulting physician, who, in an eloquent and interesting résumé of the nature and ravages of cancer, dwelt hopefully upon the future results of treatment which such an institution may afford. Dr. William H. Draper, also as a member of the medical staff, in his usual lucid and classic style, dwelt upon the noble purposes of the hospital, the liberality of the donors, and the earnest hopes of the staff. The Rev. Dr. John Hall also made an address, in which he eulogized the purposes of the hospital. The opinion of the large number of visitors was unanimous in regard to the institution, as being the best constructed and most perfectly equipped one of its kind to be found anywhere.

Applications for the admission of patients can be made to Mr. Ford, the superintendent of the hospital, or to any member of the medical staff.

THE CONTAGIOUSNESS OF CANCER.

THE question of the contagious or infectious nature of cancer is continually recurring. The *Lancet* has recently started a discussion bearing upon it by a citation of three cases in which epithelioma of the penis in the husband has been followed by cancer of the cervix in the wife. Mr. Clement Lucas, referring to these cases, reports a curious instance of three different forms of cancer occurring in three individuals living together in the same house. He says: "In 1881, and again in 1883, I operated on a gentleman suffering from rodent ulcer of the eyelid and forehead. He is still living, but with a return of the growth. In 1884 I operated on his wife for scirrhus of the breast; and during the past week a partner, who has always lived in the same house with them, has come under my care with epithelioma of the tongue. I would not suggest that there is of necessity anything more than accidental association between these cases.

but the coincidence is the more interesting in that there is no blood relationship between them. Before one has learned to attribute the ravages of cancer to the introduction of some external virus, one must have regard to the more apparent contributaries to its outbreak; and if asked as to these, I should give, in order, age, syphilis, melancholia, gout."

Quite apropos of this subject is a communication made by Professor Von Bergmann, at a recent meeting (November 2d) of the Berlin Medical Society, "Upon the Infectious Nature of Cancer." He reminds his hearers of the fact that many pathologists have thought that cancer belonged to the class of infectious disorders. Virchow has said that cancer of the stomach, in particular, bears the impress of an infection, and Klebs has called attention to the presence of gastric cancer in persons who had first suffered from cancer of the tongue, gums, or jaws. Kraske and Israel have cited similar illustrations. Cases of contact-carcinoma are, however, rare, and Von Bergmann presented a striking illustration of it before the Society in question. The patient suffered first from a carcinomatous nodule in the middle of the upper lip; after this had begun to ulcerate, a cancer appeared at a corresponding point in the lower lip. At the same meeting Dr. Hahn described a most interesting, though somewhat audacious, experiment which he had made upon a patient suffering from widespread deposits of cancerous nodules. Three of these he removed and transplanted. Cancer developed at the points at which they were placed.

Facts thus continually accumulate, leading to the belief that cancer is a specific infection, and that we may some day find its specific cause, be it microbe or ptomaine.

BACILLI IN HUDSON RIVER ICE.

THE *Sun* devotes a double-leaded editorial and a column of its valuable space to calling attention to the presence of bacilli in Hudson River ice. The investigations of Dr. Prudden, as published in THE MEDICAL RECORD, are quoted. There seems little doubt that the melted ice from the Hudson, chiefly used in this city, contains an unusual proportion of living bacilli. But while a few of these may at some time do harm, it does not seem that they have as yet established a very bad record. The great ice-drinking season in this city is in June, July, and August, but the typhoid-fever season does not begin until later, and is then very often imported from the country. The excess of diarrhœa in summer can hardly be attributed to the ice-water, for it occurs among infants and the poorer classes, who do not indulge much in the luxury of iced drinks. On the whole, therefore, the Hudson River ice-bacilli cannot be charged with having as yet done any great harm.

A UNIVERSAL LANGUAGE FOR SCIENCE.

WHATEVER may have been the causes which have led, almost in our own day, to the abandonment of Latin as the language of science, it cannot be denied that very great inconvenience is occasioned by the want of some medium of communication which may be used by men of all nationalities. As it is now, a knowledge of English, French, and German, while perhaps not absolutely essential, is yet of extreme importance to any physician who wishes to keep himself thoroughly up in his science. This requires the study of two languages besides the mother tongue, and one whose vernacular is none of these three must ground himself in three foreign idioms before he is thoroughly equipped for his life-work. The adoption of any one of these three modern tongues as the sole language of science is, of course, not to be thought of. A Frenchman would rather bury the fruits of his scientific labors fathoms deep than give them to the world in a Teutonic dress, and the German would be equally loath to clothe his ideas in Gallic habiliments. Neither of them could ever be induced to abandon his mother tongue for English, and the reluctance of the English speaker to adopt a foreign idiom, even were he able to do so, would doubtless prove to be equally invincible.

Latin is the one tongue the adoption of which is not rendered impossible by national jealousies, but, alas! who knows Latin now? How many of our readers can, with their hands on their hearts, affirm that they can write, without abbreviations and without grammatical errors, a simple Latin prescription? We would gladly believe that there are many, but we fear they are few in number. We need not discuss the causes for this lamentable ignorance of Latin in our day, the chief of which is the execrable methods of teaching in vogue. It is sufficient to state the patent fact that Latin is not only dead, but buried, as far as medical literature is concerned.

The need of a universal language is felt not only in the scientific, but, and perhaps even more urgently, in the commercial world. This want has impelled many thinkers to the search after some common medium of communication, and numerous are the attempts which have been made, from Leibnitz down to Stephen Pearl Andrews, to construct a simple language which might serve this purpose. All of these essays have, however, failed signally, and their authors have never succeeded in gaining any disciples, one only excepted.

There is one language, not yet ten years old, which seems to contain within itself the essentials of a universal tongue. Its grammar is extremely simple, there are but few rules, not a single exception, and each word has a definite meaning and can never be wrongly interpreted. This language, which is the invention of Father Schleyer, a Catholic priest in Constance, is called Volapük, meaning world-language. The first grammar of Volapük was published in 1879, and it is estimated that there are already more than two hundred thousand students of the language, and societies formed to promote its study exist to the number of over one hundred in the different countries of Europe. Volapük grammars can be obtained in twenty different languages, dictionaries in nearly as many, and there are upward of a dozen periodicals published in the strange tongue in the larger European cities. Furthermore, there are a number of business-houses, in Spain and France more particularly, that employ Volapük correspondents, and one store in Paris displays a sign in the window to the effect that Volapük is spoken there.

The astonishing progress that this language has made

cannot but excite wonder, and it may well give occasion also to a little reflection. The students of Volapük are not at play. Many of them are practical business-men, who have no time for trifles, and who would not undertake even the little study required to learn this tongue, unless they believed that it would prove to be of real utility to them. They have found it to meet their wants, and they encourage their clerks and others to learn it. The language is very easily acquired. Its grammar can be learned in a week, and the odd moments of a single month suffice for the acquisition of a vocabulary of good working comprehensiveness. If it is adapted to the varied requirements of a commercial language, it ought to serve equally as a medium for the expression of scientific thought. And so in fact it would, were it generally adopted by writers. It would not surprise us to find some Volapük enthusiast in France or Germany starting a medical periodical in this idiom at any time; and if every medical reader of the language were to subscribe, its circulation would be no mean one. If Volapük continues to gain students in the future as it has in the past, we may confidently expect a discussion at the Berlin Congress, in 1890, concerning the advisability of its adoption as a general medical and scientific language.

THE CONDITION OF THE CROWN PRINCE.

Judging from the press reports concerning the present condition of the Crown Prince, it would appear that there is a marked improvement in many of the local symptoms of his disease. This, however, does not imply that there has been any error in diagnosis, or that the original disease is not still present. The acute lesions, which have now happily in a great measure disappeared, were due to secondary perichondritis. Although Professor Virchow is non-committal as to the significance of the microscopical character of the growth recently submitted to him, it is quite plain to such as can read between the lines, and can appreciate the clinical points in the case, that the malignancy of the trouble hardly admits of a question.

All apparently different opinions regarding this point can be reasonably reconciled. The fact that the microscope has not demonstrated malignancy is merely negative testimony, and, in face of the constant tendency of the disease to recur, does not deserve to be taken into account.

Whatever may be the difference of opinion in regard to the expediency of a radical operation, there is every reason to believe that certain emergencies associated with the progress of the disease, such as œdema glottidis, or other inflammatory effusions, may render tracheotomy necessary. The tendency to perichondritis is an element of the disease which also favors accidental complications of grave character.

A New Section in the Academy.—A Section of the Academy of Medicine, to be devoted to the discussion of Diseases of Children, was organized on Tuesday evening, the 29th ult. Dr. J. Lewis Smith was elected chairman and Dr. J. Henry Fruitnight secretary of the Section for the year 1888. The meetings of the Section will be held on the fourth Wednesday of the month.

News of the Week.

Dr. Middleton Goldsmith, of Rutland, Vt., who died on November 26th, was a man of unusual intellectual force and of very wide learning. His relations with the medical scientific work of this city are well known. He was founder of the Pathological Society, and of the Middleton Goldsmith Course of Lectures. Dr. Goldsmith was born at Port Tobacco, Md., in 1818; was educated at Hanover College, Ind., and graduated from the College of Physicians and Surgeons at New York in 1840; held the chair of surgery at Castleton Medical College in 1844, and after residing in Castleton some ten years he located in Rutland for about two years, when he became dean of the Kentucky School in Medicine at Louisville. During the war he served as one of the brigade surgeons, at one time having charge of all the military hospitals in Kentucky; growing out of his experience in this work came a book on "Hospital Gangrene, Erysipelas, and Pyæmia." After the war he returned to Rutland, where he had been employed mainly as a specialist in surgery; at divers times he had held important positions in the State, in the line of his profession, and was regarded as an able physician and surgeon. A few days prior to his death Dr. Goldsmith gave his valuable library to the Academy of Medicine at New York.

Dr. John D. McGill has been chosen to fill the vacancy in the staff of St. Francis Hospital, in Jersey City, caused by the death of Dr. Theodore R. Varick. The choice has led to a disruption among the physicians, and Dr. B. A. Watson, one of the staff, has resigned.

A Provident Medical Association, under the title of the Mutual Medical Aid Association, has been organized in this city. An entrance fee of fifty cents, and a weekly premium of ten cents, are charged.

A case of leprosy is reported as having been recently discovered in Savannah, Ga. The patient's home was in South Carolina.

A Bill for Improving the Condition of the Medical Service of the Navy is likely to be presented to Congress soon. It will provide for better pay for the officers, and in other ways increase the inducements to enter the service. It is at present an impossibility to fill existing vacancies in the corps. There are thirteen places to be filled.

Old Primiparæ.—The *Centralblatt für Gynäkologie* has recently reviewed a thesis by Dr. A. Eckhardt on the subject of elderly primiparæ. This thesis is based upon five hundred and forty-three first labors in women over thirty years of age, observed in Schroeder's wards. Cases thus relatively old formed but two and a half per cent. of all the labors in the same clinic. They depended upon one or two conditions—lateness of the first coitus, or disease in the woman or her consort. The idea, so prevalent, that the soft parts are very rigid in old primiparæ was authenticated by Dr. Eckhardt's researches, and this condition accounted for the greater frequency, in the same class of women, of lacerations and fistulæ. Disorders associated with pregnancy were found to be more marked and frequent in old primiparæ than in the total of first pregnancies. Placenta prævia

and prolapse of the cord were "possibly" more frequent. The statistics proved that contracted pelvis, breech presentations, face presentations, and twin births were also more often seen in old than in younger primiparæ; it is not noted how the greater frequency of contracted pelvis could be explained. Retained placenta appeared more common; atony of the uterus was decidedly often observed in these cases. In primiparæ between thirty and forty years of age the excess of male births was greater than in others, while in primiparæ over forty, on the other hand, there was excess of female births. Relatively, cases of advanced ossification of the fetal cranium were rare. The editor of the article in the *Centralblatt* declared that Dr. Eckhardt had exercised great care in guarding against sources of fallacy in his statistics.—*British Medical Journal.*

Red Hawthorn in Uterine Hemorrhage.—The root of the Cratægus officinalis, or red hawthorn (Russian, *Krasny boïaryshnik*), has been from time immemorial urged by the Russian peasantry as an excellent remedy for uterine hemorrhage of all kinds. With the view of testing its value, Dr. E. M. Jdanko, of Pïatsgorsk, recently gave ("Proceedings of the Russian Balneological Society of Pïatsgorsk," August 29, 1887, p. 35) a very strong decoction of the root to a lady, aged fifty-two, who was suffering from frequent profuse floodings caused by uterine fibro-myoma, for which most of the usual hæmostatics had been tried in vain. The use of hawthorn completely arrested the hemorrhage. Dr. Jdanko therefore suggests that a fair trial should be given to this popular remedy.

Chloride of Ethylene has been shown to possess the curious property of producing corneal opacity (in dogs). The animals were made to inhale the vapors for one and a half hour. In the course of a few days the opacity developed, as the result probably of changes in intra-ocular pressure.

Antipyrin is not only a patented medicine, but there is some reason to believe that adulterated specimens are on the market. Complaints as to its falsification were recently presented to the Therapeutical Society of Paris.

Professor Virchow has made an address before the Berlin Medical Society, in which he explains and defends his statements with regard to the Crown Prince's condition. The pieces which he examined were, as he at the time stated, too small and superficial to enable a positive diagnosis to be made, and he expressed a guarded opinion at the time. He still thinks that they represent a warty growth, and states that the recently observed cancerous growths did not develop from the point from which the specimens examined were removed. The professor does not say whether he still thinks that the Prince has or has not had pachydermia verrucosa.

Blanks for Official Registration of Births, Deaths, and Marriages.—The Health Department of the City of New York has resolved "that on and after January 1, 1888, no certificates of births, deaths, or marriages will be accepted and filed in this office unless they are made out upon the new blanks, which have been prepared with special reference to binding, and have a margin reserved for that purpose." These blanks can be procured in Room 38, 301 Mott Street, or will be sent to any address on application.

Dr. Morris H. Henry.—His Imperial Majesty the Sultan of Turkey has conferred on Dr. Morris H. Henry, of New York, the decoration of Commander of the Order of the Medjidieh of Turkey, for "distinguished services in the cause of medical science."

Transferring a University.—The University of Douai has been removed to Lille, much to the disgust of the Douaisians. The first university at Douai was established in 1560.

Typhoid Fever is so prevalent in Albany, N. Y., that the mayor has issued a proclamation urging its citizens to boil all river-water before using it.—*Sanitary News.*

A Congress of Russian Physicians will meet at St. Petersburg in April, 1888.

A Practical Course in Medical Dietetics has been opened at the University Medical College in Philadelphia.

Medical Mayors.—The mayoralty seems to be an object of ambition to English doctors. The *Lancet* announces the election recently of eleven medical men to this position.

Postmen are said to be a very healthy class, except as to their eyes. Nearly all suffer some impairment of vision, to their being obliged to read in the glare of the sun. Postmen not infrequently suffer from sciatica.

The Contagiousness of Leprosy.—This question, which is constantly being raised in connection with some new series of investigations, or the appearance of the disease in some new locality, has been under discussion again lately. M. Besmer, of Paris, read a very exhaustive article on the subject before the Paris Académie de Médecine. He cites a number of cases in which contagion occurred, and urges the importance of the segregation of lepers. The London *Times*, in an editorial upon the matter, states "that during the last fifteen years the total number of lepers in England has not exceeded fifty or sixty, and that in no instance has the disease spread. A recent report of the College of Physicians supports the views of the writer in the *Times*. This report, which is dated July 15, 1887, states that 'the committee are of opinion that if there be any elements of contagion in leprosy, they are not more to be dreaded than are those in the case of syphilis, which is not commonly considered to justify segregation on the part of those affected, and that they believe that leprosy is not contagious in the conventional sense of the term, but if at all, is only so in low degree and under exceptional circumstances.'" This, we believe, represents the general opinion of the profession. Still, as long as there is a possibility of the disease being conveyed to others, and as long as segregation is neither impracticable nor inhuman, it is, perhaps, the safest plan to adopt it.

Dentistry for the Poor.—There is no better field for humanitarian work than in providing some means whereby the poor can have their teeth properly treated at small or no expense. At present most of the dentistry in this city which is done gratis is in the line of tooth-pulling.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE,

Stated Meeting, December 1, 1887.

A. Jacobi, M. D., President, in the Chair.

The President acknowledged the receipt, through the kindness and influence of Dr. John C. Peters, of the library of the late Middleton Goldsmith, M.D., of Rutland, Vt., consisting of nearly six thousand volumes.

The President announced the following as

THE COMMITTEE ON CONFERENCE WITH THE BOARD OF HEALTH:

Drs. C. R. Agnew, R. H. Derby, Stephen Smith, E. G. Janeway, and, elected by the resolution providing for the committee, A. Jacobi.

The President appointed the following

MEMORIALISTS

of the late T. R. Varick, M.D., Dr. J. Leonard Corning; Alonzo Clark, M.D., LL.D., Dr. Francis Delafield; Middleton Goldsmith, M.D., Dr. John C. Peters.

Professor James Law, F.R.C.V.S., of Cornell University, was invited to the platform, and introduced to the Academy.

Several reports of Sections were then read.

The Academy then proceeded to the

NOMINATION OF OFFICERS.

Vice-Presidents—Andrew H. Smith and E. L. Keyes; *Trustees*—D. B. St. John Roosa and G. M. Smith; *Treasurer of Trustees*—F. A. Castle; *Committee on Admissions*—R. C. M. Page, E. L. Partridge, J. S. Warren, O. B. Douglas, and A. J. C. Skene; *Committee on Library*—short term—D. B. Delavan and H. Griswold; long term—T. M. Cheesman, Jr., Daniel Lewis, G. H. Fox, P. A. Morrow, W. Mendelson, M. Allen Starr.

Dr. J. W. Stickler, of Orange, N. J., then read a paper [see p. 725] on

THE PROPHYLACTIC RELATION OF THE FOOT-AND-MOUTH DISEASE TO HUMAN SCARLATINA.

In the discussion, Dr. Andrew H. Smith said it seemed that Dr. Stickler had made out an excellent case for the probability of protection being afforded by inoculation. He inquired whether or not the foot-and-mouth disease occurred sufficiently often in this country to be made available for the purposes indicated.

Dr. Stickler replied that it could be reproduced with very great readiness. The disease that occurred upon the Hendon farm, England, did not occur with such frequency.

Dr. Smith thought it worthy of consideration that the same result might occur as with small-pox, when animals were inoculated with that disease—namely, that the human subject when inoculated with the virus from those animals had small-pox.

Dr. L. McLean, Government Veterinary Surgeon, said that the foot-and-mouth disease never occurred as an epidemic but as an epizootic in Scotland, where he had been familiar with it for many years.

In the *bovine* species, also, one attack did not give immunity from the disease; but in the *ovine* species it did.

He did not believe that the foot-and-mouth disease had been found in the West in this country, as the author of the paper had stated. Besides, the temperature, 101° to 102° F., mentioned by Dr. Stickler as febrile, was the normal temperature of the bovine tribe. Cattle that were stall-fed, particularly, always had that temperature. So it must not be concluded that an abnormal condition was present simply because the thermometer showed a temperature of 102° F. To repeat, the *epizootic aphthæ* did not confer immunity from a second attack in the bovine species; but he had never seen a sheep with a second attack, and he had had extensive opportunity to study the disease.

Dr. J. E. Stubbert, of Bloomfield, N. J., gave the details of the clinical history of one of the cases referred to by Dr. Stickler in his paper, which showed that it was scarlet fever.

Professor Law was quite sceptical concerning the prophylactic influence of the foot-and-mouth disease, of which he had seen a great deal in Europe, against scarlet fever. Epizootic foot-and-mouth disease had at times attacked nearly all the cattle and the people, and, considering the fact that the disease was so frequently prevalent, there should be less scarlet fever in Great Britain than in America, where the foot-and-mouth disease was comparatively unknown. But, so far as he knew, scarlet fever prevailed and was rather fatal in Great Britain,

NINETY THOUSAND DYING OF THE DISEASE IN FIVE YEARS,

which did not speak very loudly for prophylaxis.

Again, the fact that the foot-and-mouth disease conferred so short-lived protection in cattle seemed to argue against the theory that it could protect the human species against scarlet fever. Whole herds of cattle had been attacked the second time within six months after the first attack, showing that it was not merely isolated cases in which the second attack occurred.

It was, perhaps, the most contagious malady known, yet the poisonous element did not extend very far into the atmosphere. So if there was no direct contact, the probability was that it would not be conveyed from one to another, and in that he thought the disease differed from scarlet fever.

His personal experience, also, tended in the direction of scepticism. For he had been exposed again and again to the foot-and-mouth disease and had never contracted it, while the very first time he was exposed to scarlet fever he took the disease. It would seem, therefore, that he was susceptible to the one and insusceptible to the other. He was the only member of a family of five which was exposed in that way that took the scarlet fever, which would seem to militate against the idea that one disease acts as a protective against the other.

As to experimentation with the foot-and-mouth disease, he believed that

IT SHOULD BE DONE ON THE OTHER SIDE OF THE ATLANTIC.

There were fifteen hundred million dollars' worth of cattle in the United States, and there would be a terrible hue and cry should experimentation with the foot-and-mouth disease be carried on here.

With regard to the prophylaxis of scarlet fever proper, supposing that it could be done, might it not be the means of spreading that disease? He feared that Pasteur, great and good as had been his work, had contributed to the spread of anthrax by sending broadcast attenuated virus.

FOR THE ATTENUATED VIRUS COULD BE RENDERED POTENT

and dangerous, and, therefore, a word of caution with regard to the cultivation of the virus of the foot-and-mouth disease might be proper.

Dr. John C. Peters had always regarded the foot-and-mouth disease as a contagious eczema. He had from the first been interested in Dr. Stickler's experiments, and felt sure that they would be continued, and that ultimately he would be rewarded with undoubted success. Dr. Peters exhibited a tube that showed the growing germ, together with copies of the *British Medical Journal* containing illustrations and articles by two Edinburgh experimenters, Drs. Jamieson and Edington.

Dr. J. Lewis Smith said that since the time of Jenner the hope has been awakened that some of the other fatal infectious diseases, and especially scarlet fever, might be prevented, as small-pox has been, by the inoculation of a milder and modified disease derived from the lower animals. As regards scarlet fever, two propositions of great interest and importance have arisen. First, is there a disease in the bovine race which is true scarlet fever, or which communicates genuine scarlet fever to man? And secondly, if there be such a disease, does it produce a mild and modified form of the disease in man?

Many instances had been recorded, in the last five or six years, in which epidemics of scarlet fever had arisen from the use of milk infected with the scarlatinous germ after the milking, and furnished from healthy cows; but in the St. Marylebone and Hendon epidemic, occurring two years ago and described in the *British Medical Journal*, May 29, 1886, the outbreak of scarlet fever appeared to be traced clearly to diseased cows. The point he wished to call attention to was this: The sickness of the cows was mild, not impairing their appetite, nor diminishing their milk; but the disease which the use of the infected milk produced had been described as an "intense outbreak of scarlet fever." Instead of a mild disease being propagated from the cow, for which we were looking and hoping, the reverse occurred. A mild form of disease in the cow produced a severe one in man, so that we might, if we inoculated with the bovine scarlatinous virus, produce a severe instead of mild scarlet fever.

Dr. R. A. McLean, Government Veterinary Surgeon, could not admit that it had been proved that scarlet fever had been contracted from cattle. Most veterinarians denied its occurrence. Unless there was direct inoculation of the animal from the human subject the occurrence of scarlet fever in animals must be exceedingly rare.

Typhoid fever did not occur in animals, and yet, through the agency of milk, that disease had been communicated, but it had been found that the water with which the cans had been washed was polluted. Milk-cans and other utensils, it had been known, had been washed and dried in rooms where children were ill with scarlet fever and diphtheria, and it seemed very probable that the poison was spread through such carelessness and lack of proper precautions.

That the author of the paper could produce scarlet fever in animals he would grant, but that scarlet fever could be produced in the human subject by inoculation with the virus of the foot-and-mouth disease he did not believe was possible to prove. For veterinarians believed that the foot-and-mouth disease was due to a specific germ, as specific as that of small-pox, and he did not believe that more than two cases of it had occurred in this country. One was the case referred to by the author of the paper, which occurred in Maine two years ago, and the other was a year prior in the neighborhood of Poughkeepsie.

The particular point which he wished to make was that the Academy should have it made known to it that the veterinary profession,

BOTH IN EUROPE AND IN AMERICA,

did not believe that the disease which occurred upon the Hendon farm was scarlet fever in cattle.

Dr. John C. Peters said that all the best authorities in veterinary medicine, as Williams and others, admitted the occurrence of scarlet fever in cattle and horses.

Professor Law said Dr. Peters' statement should be qualified in this way. Williams and others wrote of scarlet fever in cattle and horses, because the name, unfortunately, had been given to the disease, but they recognized it as

A NON-CONTAGIOUS AFFECTION,

and not identical with that occurring in man. There was no evidence that it was communicable from horse to horse, much less from animals to man.

Dr. Peters remarked that Percival regarded the disease as scarlet fever.

Professor Law said that Percival was one of the oldest writers on veterinary medicine, but the profession latterly did not recognize it as a contagious disease.

Dr. Stickler, in closing the discussion, said that he was very much obliged to the veterinarians and others for coming to hear and to discuss his paper. With reference to the foot-and-mouth disease occurring in the West, he had been told that it occurred in that part of the country.

With regard to temperature, spoken of by Dr. McLean, that of the cow in question was 100° F. before, and 102° F. after, the inoculation, and he therefore regarded it as a febrile movement.

As to the spread of the disease he could conceive that it might be true, but it did not seem to him to be objectionable if a mild form of scarlet fever could be produced; it would be beneficial rather than detrimental, because scarlet fever, as it commonly occurred, was a much dreaded disease.

Concerning the occurrence of scarlet fever in cows, he regarded the fact that cattle inoculated with scarlet fever had a disease which was exactly like that which the cattle had upon the Hendon farm, as an argument in favor of the view that it was scarlet fever which those cows had.

The Academy then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, November 28, 1887.

Laurence Johnson, M.D., President, in the Chair.

The President called the meeting to order, after the adjournment of the adjourned annual meeting, and made a few introductory remarks in lieu of the inaugural address on assuming the duties of his second term in office.

He also announced the deaths of Drs. Woolsey Johnson, James Knight, and William M. Chamberlain, after which he appointed the following

COMMITTEES FOR THE ENSUING YEAR:

Committee on Hygiene—Dr. C. E. Billington, chairman; Drs. W. A. Ewing, L. Emmett Holt, J. E. Winters, and George T. Elliot.

Committee on Ethics—Dr. W. H. Katzenbach, chairman; Drs. E. A. Maxwell, Robert Campbell, C. E. Bruce, and Charles Milne.

Prize Essays—Dr. Joseph D. Bryant, chairman; Drs. A. B. Judson, and F. A. Castle.

Auditing Committee—Dr. P. A. Morrow, chairman; Dr. H. G. Piffard.

Dr. Daniel Lewis then read a paper in which he gave the detailed history of a case of

MALIGNANT TUMOR IN AN UMBILICAL HERNIAL SAC, WITH REMARKS ON THE ETIOLOGY OF CANCER.

It was the only recorded case, so far as he had been able to ascertain, in which malignant disease had developed in an old hernial sac; and its appearance therein was regarded as new evidence in favor of the view that perfectly non-malignant diseases might prove to be the exciting cause of cancer. His definition of cancer included any neoplasm that exhibited resistance to all known medicinal agents for cure, which showed a proneness to invade other organs and tissues of the body, possessed a liability to recur after removal, was painful, and had a tendency to destroy life. Any tumor possessing these clinical features, not necessarily all of them, was malignant.

He entered his protest against the practice of trying the effect of mild caustics, for they nearly always stimulated the progress of the disease.

Dr. Webster referred to a number of cases in which malignant or cancerous growths had been present in the eye, or its appendages, secondary to the irritation of benign affections or traumatism. For example, there was one case of epithelioma of the lachrymal sac and duct following dacrocystitis.

Dr. A. F. Currier thought that the clinical diagnosis might be sufficient in many cases, but that it would not give a scientific classification or diagnosis, which must be based upon the pathological histology of the new growths. He agreed with Dr. Lewis as to the origin of cancerous disease, and believed it to be due to irritation, either primary or secondary.

EPITHELIOMA IN MOST CASES

began in local irritation, and when treated in that stage it was amenable and could be cured. He cited cases of uterine cancer which showed the good effect of the local use of *alveloz*.

The President mentioned a case which forcibly illustrated the production of malignant disease by direct irritation.

Dr. Carpenter asked Dr. Lewis if he regarded all tumors that did not exhibit the clinical features mentioned as non-malignant.

Dr. Lewis replied that he did.

Dr. Carpenter referred to the cancerous tumors occasionally found accidentally in the stomach and omentum, which had never given rise to any symptoms.

Dr. Lewis regarded those cases as sufficiently exceptional not to invalidate the general clinical diagnosis he had indicated.

It was not the object of his paper to make a classification, but to point out the clinical features which warranted the diagnosis of malignant disease without the aid of the microscope.

Dr. Robert T. Morris read a paper entitled

A FEW PRACTICAL REMARKS ABOUT BUNIONS,

with special reference to hallux valgus. He advocated dissecting out the sac, in some cases excision of the head of the bone, and the use of what he termed a compartment-shoe; that is, a shoe with a loop on the inside, fastened to the welt, into which the toe could be put and held in position.

Dr. Carpenter spoke of the relief, in cases of the smaller bunions, to be obtained by bathing the foot once or twice a week and rubbing off the superficial epithelium completely with the fingers. The tendency to the formation of a corn upon the bunion might in that way be prevented. Of course, pressure from boots or shoes must be avoided, as it was very likely to be, because of the exquisite tenderness of some of these formations, which were very good indicators of the approach of a storm.

The President spoke of the influence of barometric pressure on these painful joints, and also affections rheumatic or gouty in character.

Dr. A. M. Phelps favored excision of the sac, and also the head of the metatarsal bone.

Dr. Corning exhibited plates illustrating sections of an immense corn which he had had opportunity to work up while in Europe.

The Society then adjourned.

Copper and Consumption.—Professor Luton, of Rheims, in a long article, concludes that a cure of tuberculosis can always be effected by means of the phosphate of copper, which, however, must be in the nascent state and soluble in an alkaline body. He thinks he has found a specific in the following formula: Neutral acetate of copper, gr. .15; crystallized phosphate of sodium, gr. .75; glycerine and powered licorice, each, a sufficient quantity. This for one pill.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 26, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. G. C. Freeborn, from the Committee on Microscopy, reported on

THE INCRUSTED INTUBATION-TUBE

presented at the last meeting by Dr. H. J. Boldt.

"The incrustation proves, on micro-chemical examination, to be calcium carbonate mixed with a large percentage of organic matter. The polish of the gold-plating is perfect except in the immediate vicinity of the deposit. Around the spots of incrustation, for a small fraction of an inch, it is roughened, and appears as if it had been acted upon by some corrosive agent. In no place uncovered by the incrustation was the plating wanting, though in a few spots it appeared, on examination with a magnifying-glass, as if it had been scraped with a rough instrument."

[At the meeting held on November 9, 1887, Dr. Freeborn made the following supplementary report:]

"On removing the deposit of lime salt, by means of hydric chloride, the gold-plating underneath was found, upon examination with the microscope, to be perfect, and the appearance of corrosion, described above, was probably due to a thin deposit of lime salt.

"Experiments were also made with solutions of mercuric chloride, varying in strength from 1–2,000 to 1½ per cent. These solutions were applied to the gold-plating of the tube, and allowed to remain in contact with it from ten to thirty minutes. The tube was then washed in distilled water, and upon microscopical examination no erosion or change in the character of the gold-plating could be detected."

Dr. Freeborn further reported on the specimen of

"MULTIPLE ULCERS" OF THE BLADDER,

presented by Dr. Northrup, that, on microscopical examination, they were found to be *diverticula* of the bladder.

Dr. W. P. Northrup made the following supplementary report on the specimen presented by him on September 14, 1887:

"The numerous small, round, punched-out excavations, having a deep-red base and wall, had been found, on microscopic examination, to be not ulcers, but diverticula. The discoloration was post-mortem. On section, the mucous membrane of the bladder was found to wind around the sharp edge of the excavation, follow the wall of the undermining cavity and traverse the base and opposite wall, and become again continuous with the mucous membrane of the bladder.

"The following was the best explanation they had been able to find of this condition: Whatever obstructs the flow of urine, such as stricture or enlarged prostate, tends to hypertrophy of the bladder-wall. 'The muscular coat is thickened uniformly, or assumes a trabeculated appearance.'[1] As to the diverticula, 'they are produced by a protrusion of the mucous membrane between hypertrophied bundles of muscle-fibres.'

"Pressure has forced the mucous membrane out between these hypertrophied bands, forming pouches or herniæ of mucous membrane.

"As to the *hæmaturia*, the only explanation they could offer was that of diapedesis. 'Without recognizable changes in the walls of the vessels, all the elements of the blood might become extravasated by passing without rupture through the walls of the vessels,'[2] under certain conditions. There was no post-mortem evidence of any rupture of vessels nor ulceration, now that the diverticula were explained."

Dr. W. M. Carpenter remarked that it was a recog-

[1] Delafield and Prudden: Handbook of Pathological Anatomy and Histology.
[2] Ibid.

nized principle in surgery *not* to empty the bladder wholly at once in cases of retention of urine of several hours' duration, because of the liability to the occurrence of hemorrhage by diapedesis.

Dr. W. P. Northrup presented, in behalf of a candidate, a specimen of

CARIES OF THE SPINE.

Dr. A. P. Dudley presented a specimen of

MATERIAL REMOVED FROM THE CAVITY OF THE UTERUS,

with the following history: The woman was sixty-five years of age, and the mother of four children. All her labors were normal. She passed the menopause thirteen years ago without accident. About three years ago she lost her husband suddenly, and she did not recover from the shock for a long time. About two years ago she began to have uterine hemorrhage, which had continued more or less constant—slight flow for a few days, and recurring after a short interval—until last July, when it became profuse. She brought with her the diagnosis of uterine fibroid, but Dr. Dudley was unable to obtain any evidence of that affection. The uterine cavity was only three inches deep; the os and cervix showed no lesion. There was no evidence of peri-uterine disease. There had been no odor to the blood at any time. There had been but little pain, except pain in the back. There had been no loss of flesh, and there was no cachexia.

Dr. Dudley dilated the uterus rapidly and removed the mass presented, which

COVERED THE ENTIRE INTERNAL SURFACE OF THE ORGAN.

Dr. H. C. Coe had examined a portion microscopically, and reported that it had the appearance of fungosities; it might be a myxomatous polypus that had undergone degeneration, and it was possible that it might be an adenomatous growth; but he was unable to find any evidence of malignant disease. The woman had had one hemorrhage since the operation, which was performed a week ago, but it ceased at once on washing the uterus out with hot carbolized water, and the washing brought away a small piece of material such as was removed at the operation. Dr. Dudley had not encountered a similar case, and had had grave apprehensions concerning its possible malignant character.

Dr. Dudley also presented a specimen of

HÆMATOMA OF THE OVARY,

removed one week ago from a patient twenty-two years of age, who had been under his care for one year, during which time he adopted a great variety of general internal treatment, with local internal and external applications; but the woman was not relieved a particle of the constant pain in her left side, which increased in severity with each return of her monthly sickness.

An exploratory incision was made, the left ovary easily lifted and removed, and on opening it there was found a hæmatoma that occupied nearly the entire organ, which was not of frequent occurrence. The patient was convalescing, and, thus far, had not suffered from the pain of which she formerly complained.

Dr. W. M. Carpenter mentioned a case which was almost identical with the one first reported by Dr. Dudley. A woman who had passed the menopause ten or twelve years was profoundly shocked by the death of her husband, and began about two months thereafter to have slight uterine hemorrhage, which continued more or less constantly for more than a year, with one profuse flow, and attended only by backache. The discharge was odorless, and there was neither loss of flesh nor cachexia. Dr. James B. Hunter took charge of the case; found no evidence of disease of the cervix or peri-uterine tissues, nor any evidence of uterine fibroid. He dilated the uterus, and removed a mass of material which, from the description, was like that described by Dr. Dudley. Since the operation there had been no hemorrhage, and the patient, thus far, had remained well.

Dr. Mary Dixon Jones mentioned a case of recurrent uterine hemorrhage, occurring after the menopause, in which she effected a cure by dilating and curetting the uterus.

TUBERCULAR MENINGITIS—AN OLD CASEOUS NODULE IN THE BRAIN.

Dr. L. Emmett Holt presented a specimen with the following history. The specimen was referred to the Committee on Microscopy.

It was taken from the body of a female child, aged four, who died at the New York Infant Asylum after ten days' illness. The parents were healthy, but the mother's family was tubercular. The child was plump and healthy in appearance up to the beginning of the last illness. The onset was gradual, being characterized by listlessness, anorexia, drowsiness, and constipation, but no vomiting or headache.

The symptoms were typical after the first three days. There was abdominal retraction, well-marked *tâche cérébrale*, loss of knee-jerk, slow, irregular pulse, Cheyne-Stokes respiration, opisthotonos, dilatation of the pupils, and semi-stupor, which merged into true coma. For the first four or five days there was almost complete left hemiplegia, with greatly diminished sensibility upon the same side; this did not disappear, but the opposite side gradually became affected to the same degree.

There were no convulsions, hydrocephalic cry, or vomiting. The temperature was from 100° to 101.8° F., until two days before death, when it ran up rapidly to 104° F. Death took place quietly.

Autopsy, two hours after death. Body well nourished.

Head: The brain was intensely engorged, the convolutions flattened. There were no tubercles or signs of inflammation except at the base, especially abundant over the frontal lobes, in the interpeduncular space, and along the great longitudinal and Sylvian fissures; here they matted the tissues together quite firmly. Inflammatory products about equally distributed over the two sides. In the left Sylvian fissure, just internal to its bifurcation, was a caseous nodule, the size of an ordinary grape, which seemed to be meningeal in its origin and connections. The ventricles were dilated, each containing about an ounce of clear serum; ependyma congested, no tubercles seen. Spinal cord not examined.

Thorax: The lungs were healthy; no tubercles. The bronchial glands were cheesy, and as large as beans. The heart-auricles were distended with black clots; no endocarditis; no tubercles in pericardium.

Abdomen: A very few tubercles were scattered over the surface of the liver and spleen; none were found elsewhere, though careful search was made. The intestines were normal, except some recent congestion in the colon. The mesenteric glands were not cheesy.

The other organs were normal, except the kidneys, which showed some cloudy swelling. No disturbance of speech was observed during life.

Dr. W. H. Porter presented a specimen of

STRANGULATED BUBONOCELE

with a peculiar history. The man from whose body it was removed was a waiter, between thirty and forty years of age, in whom developed suddenly the active symptoms of strangulated hernia. When a physician was called he found a large and painful tumor in the right inguinal region, and also a large tumefaction of the scrotum. The man was suffering with intense pain, had vomited stercoraceous matter, and was constipated. The physician applied taxis and caused the rapid disappearance of the scrotal tumor. But the symptoms of strangulated hernia continued, and he made repeated attempts by taxis to reduce the tumor in the inguinal region, but failed. The patient became partially moribund, and in that condition

was transferred to the hospital, where he died soon after admission.

At the autopsy the knuckle of intestine presented was found in the inguinal canal. About one pint of bloody serum was found in the peritoneal cavity, and it was also found that the tunica vaginalis had been ruptured. It was believed that through the rupture in the tunica vaginalis the fluid of

THE ACUTE HYDROCELE

had been forced upward into the peritoneal cavity by the taxis. The peritoneum covering the strangulated portion of intestine remained bright and glistening, and there was no evidence of peritonitis.

DR. IRA VAN GIESON presented a specimen of

MULTIPLE DIVERTICULUM OF THE BLADDER, ONE OF WHICH CONTAINED A NUMBER OF SMALL URINARY CALCULI.

The bladder was removed from the body of a patient who died in Charity Hospital. Its inner surface was perforated by five apertures, ranging from 3 to 8 mm. in diameter, leading into irregular-shaped cavities in the wall of the bladder. Back of the urethral orifice, in the posterior wall of the bladder near the median line, was an ellipsoidal diverticulum, 1 by ¾ ctm. in diameter, distended by white calculi, over 110 in number, about the size of shot. The calculi caused a slight bulging forward of the mucosa, and the orifice by which the diverticulum communicated with the interior of the bladder was so small that it escaped observation. The right kidney was small, measuring 3 by 1½ ctm. in diameter, and reticulated, but seemed normal. The left kidney contained a calculus in the pelvis, about the size of a pea.

There were no symptoms referable to the bladder. The point of interest was the presence of these little pockets, which favored the formation and retention of small calculi in the mucous membrane of the organ.

THE PRESIDENT remarked that the specimen was especially interesting in connection with the one presented by Dr. Northrup. In one case there was hemorrhage by diapedesis, and in the other an accumulation of small vesical calculi in these diverticula in the mucous membrane.

The Society then went into executive session.

THE LATE THOMAS J. I. FORD.—At a special meeting of the Medical Board of St. Vincent's Hospital, held on Monday, November 21, 1887, the following resolutions were adopted as a mark of respect to the memory of Dr. Thomas J. I. Ford, late Visiting Physician to the Hospital:

Resolved, That the members of this Board, while bowing to the will of an inscrutable Providence, cannot but express their profound sympathy and regret at the sad demise of their late associate, Dr. Thomas J. I. Ford, who, by his faithful devotion to the interests of the Hospital and his unremitting attention to patients under his care, had won the respect and esteem of his associates.

Resolved, That the Board extends to the family of the deceased its earnest sympathy for them in their bereavement, and assures them that its members share in the deep sense of personal loss which Dr. Ford's death has occasioned.

Resolved, That a copy of these resolutions be published in THE MEDICAL RECORD, and sent to Mrs. Ford.

M. K. HOGAN, M.D.,
Chairman.
CONSTANTINE J. MACGUIRE, M.D.,
Secretary.

VOLKMANN'S ANTISEPTIC LIQUID.—Thymol, 1 part; alcohol, 10 parts; glycerine, 20 parts; water, 100 parts.

OUR LONDON LETTER.

(From our Special Correspondent.)

SIR JAMES PAGET ON CANCER—HERNIA IN MONKEYS—QUIET IRITIS—THE PRESYSTOLIC BRUIT—THE PARKES MUSEUM OF HYGIENE.

LONDON, November 19, 1887.

THE Morton Lecture on Cancer at the College of Surgeons is one recently established, and Sir James Paget was selected to deliver the first lecture. He commenced it by saying that we might safely believe that Mr. Morton, in generously founding the lectureship, entertained the hope that it might lead to some distinct practical utility, perhaps to the discovery of a method of prevention or cure of cancer. We might hope to find a remedy in the constant careful study of the likeness of cancerous diseases to others for which we already had means of useful treatment. We might be the more hopeful, because the nearest likenesses of cancer and cancerous diseases were to two other groups of diseases concerning which there had been, in recent times, very useful additions to our knowledge. In one direction we had their likeness to the simple or innocent tumors, in the surgical removal of which the risk to life had been diminished; and in the other direction their much more intimate likeness to some of the specific and micro-parasitic diseases, a group in which progress had been made toward both preventive and remedial treatment. Cancerous diseases agreed with the simple or innocent tumors in that they were all structures growing with some degree of likeness to the natural structures of the body, especially of the part in which they were placed, but growing as if with a self-possessed power of maintaining and increasing themselves. This purposeless, selfish method of growth was characteristic of both innocent and cancerous tumors. The lecturer defended the term "malignant," for the qualities which it indicated were far more distinctive and more surely diagnostic of this group of diseases than the minute structure and chemical composition of the diseased parts or even their method of growing. In this was an example of what we must hold in the study of all diseases, for pathology was a part of biology and not derived chiefly from the study of anatomy and chemistry. It was by the biological characters of cancerous diseases more than by the histological and chemical characters that their affinities to the innocent tumors on the one side, and to the specific diseases on the other, might be judged. Every year's study made it more probable that each specific disease was due to the influence of a distinct morbid substance on some part or parts at which the characteristic signs of the disease could be manifested. Two conditions must coincide in each; the one general or diffused in a morbid material in the blood; the other local, in some part with which this material produces disease.

Sir James Paget said he believed that micro-parasites or substances produced by them would some day be found in essential relation with cancers and cancerous diseases. The specific diseases known to depend on morbid materials in the blood were very numerous. They might be vaguely arranged in groups, and the group by which the conformity of cancers and cancerous diseases might be tested was one which included, as its chief members, syphilis, tuberculosis, glanders, leprosy, and actinomycosis, each of which was known to have a distinct micro-parasite. After pointing out the most important general agreements of these diseases the lecturer observed that, as we know that in tuberculosis, syphilis, leprosy, and the rest, there is for each a specific morbid material in the blood, so we should believe that there is at least one in cancer and cancerous diseases. The fact of its not having been found was not sufficient to prove that it did not exist. After drawing some admira-

ble illustrations from vegetable pathology, the lecturer proceeded to consider at some length the manner in which cancers began. We spoke of parts "becoming cancerous," he said, and the term had been taken by some as implying that the beginning of a cancer was altogether local, and that the textures of a part might, as it were, of themselves, or through some common irritation or degeneracy, or in the course of syphilis or other diseases, change themselves and become cancerous. But in many persons these irritations and degeneracies were quite ineffective, and the facts observed were quite consistent with the much more probable belief that these degenerative changes only made the parts less able to maintain themselves, and less able to resist the invasion of any morbid material in the blood brought in contact with them. Some striking illustrations of selection of site were drawn from other specific diseases. Thus, tetanus, said the lecturer, was due to a bacillus, and this, or some material produced by it, was carried in the blood to every part, but seemed harmless to all till it reached the spinal marrow. In the sequelæ of fevers the morbid poison present in the blood affected only certain parts. In concluding, Sir James Paget urged the importance of discovering the specific morbid material of cancer and of dealing with it generically as others have been dealt with.

At the last meeting of the Pathological Society Mr. Bland Sutton exhibited two specimens of congenital inguinal hernia in monkeys. He remarked that if a patent funicular process predisposed to hernia it should be very frequent in monkeys. Mr. Jonathan Hutchinson, Jr., observed that though he had had the opportunity of examining many monkeys, he had never met with an inguinal hernia, though he had often demonstrated the patent funicular process. The observation militated against the theory that a long mesentery was the determining cause of inguinal hernia in man, for in monkeys the mesentery was always long, yet hernia was extremely rare, as Mr. Sutton had stated.

At the Ophthalmological Society's meeting Dr. Seymour Sharkey read a paper on a case of cortical and subcortical disease of the occipito-angular region producing hemianopia. Mr. Nettleship read one on the value of iridectomy in relapsing iritis, and among the remaining communications was one by Mr. J. Hutchinson, Jr., in which several cases of iritis were described in which the attack, sometimes leading to extensive adhesions to the lens, and involving much deterioration of sight, was from the first unaccompanied by the typical features of inflammation. It was, he said, not sufficiently known that iritis in certain cases did not reveal its presence by the characteristic frontal pain, and was practically unattended by congestion or photophobia.

Considerable discussion has lately taken place on the subject of the presystolic bruit. Owing mainly to the labors of Gairdner, Broadbent, Bristowe, and others, this is now pretty generally recognized as indicative of a constriction of the mitral orifice. The exact manner of its production has, however, been disputed. Dr. Dickinson has lately revived the notion that it is really a regurgitant murmur, but, although supported by Dr. John Harley and Dr. Charlewood Turner, the statements he has put forward have not been received with much favor, and the older view of its being really a murmur caused by the onward flow of blood through the stenosed orifice bids fair still to hold its ground.

There is some ground for apprehension that the Parkes Museum of Hygiene may have to be closed for want of funds. It was founded some years ago as a memorial of the late Professor Parkes, and is the only institution in this country of its kind. It is, therefore, sincerely to be hoped that funds may be forthcoming to continue its existence. Efforts are being made to obtain them.

Berlin Physicians.—The proportion of physicians in Berlin, to the population, is about one to one thousand.

OUR PARIS LETTER.

(From our Special Correspondent.)

CURIOSITIES IN HYPNOTISM AND AUTO-SUGGESTION—ANTIPYRINE IN UTERINE COLIC.

Paris, November 25, 1887.

The phenomena of hypnotism or mesmerism are creating a great sensation in this country, both among the profession and the general public, and so long as they are practised as a source of amusement for the latter nothing can be said against them; but, as they threaten to enter the domain of medicine, it is time that serious notice should be taken in order to ascertain the real value of these phenomena, particularly as regards their application as therapeutic agents. The latest phenomenon of hypnotism that has been brought before the profession is that known by the term "suggestion," one exemplification of which is the action of medicines at a distance, that is to say, one has only to apply or hold up at a distance from the patient, or from any part of his or her body, a medicinal substance, accompanied, of course, by a hint of its physiological action, and the desired effect is produced. It will be remembered that Dr. Luys, an *agrégé* of the faculty of medicine of Paris, and Physician to the Salpétrière Asylum, recently read a report before the Academy of Medicine, of certain experiments he had performed on some female patients, with different medicines in sealed tubes, which he applied as above described, and obtained the results anticipated. The Academy, however, not willing to lend itself to such medical jugglery, ordered a commission to investigate the matter before forming an opinion as to its merits. The result is not yet known, but it may be observed that these extraordinary phenomena have been obtained on hysterical patients who have been hypnotized or put into a state of somnambulism.

Meanwhile, Dr. Constantin Paul had invited Dr. Bourru, of Rochefort, who had acquired a certain notoriety in this direction, to repeat the experiments announced by him, in his hospital ward. At a recent meeting of the Société de Thérapeutique, Dr. Constantin Paul stated that he had placed at Dr. Borru's disposal a most sensitive subject, upon whom he was allowed to act without any extraneous influence. With a bottle of alcohol uncorked, staggering was produced; but this effect was not considered satisfactory, and Dr. Paul observed that the proceeding was not correct, as the emanations from the uncorked bottle containing the alcohol would suggest to the subject under observation the nature of the contents of the bottle, as in such a patient (a young woman), who was evidently hysterical, the sensitive faculty would amount to hyperæsthesia, and the perception of odors is certainly more acute. In another instance a bottle, supposed to contain cherry-laurel water, and held at the back of the head, produced effects usually caused by this drug; but it was discovered that, by inadvertence, intentional or otherwise, the pharmacien in attendance had put in water only. Five or six other experiments gave results of the same value. Dr. Bucquoy was equally incredulous, and said that he was afraid that the commission appointed by the Academy would throw but little light on the subject in question. He could, however, affirm that those of his colleagues and the internes who attended the séance given by Dr. Luys at the Charity Hospital, left the place with the conviction that Dr. Luys had been imposed upon.

In reference to the same subject, which was discussed at the Medico-Psychological Society, Dr. Jules Voisin attributed the results to suggestion, auto-suggestion, and the vivacity of the memory in hypnotic sleep. Upon applying an empty phial to the neck of one of his subjects, and leading her to suppose it contained alcohol, she immediately showed signs of intoxication. He then pretended to employ other phials, but always reserving the empty one to apply it to the patient, he announced the different effects of strychnine, cherry-laurel water, valerian, pilocarpine, and of the sulphate of soda, and

the phenomena announced were produced. Two months later the experiments were repeated, and putting the patient to sleep, Dr. Voisin remarked, in an audible tone, that she would be able to distinguish the drugs the one from the other. As before, he pretended to change the phial, and presented an empty one each time. The characteristic effects of the drugs were again produced, and that *in the same order*. Drs. Bourru and Burot, who patronize hypnotism, do not accept the explanation given by Dr. Voisin and others as to the mechanism concerning the results obtained, but ascribe it to "a special energy in the superior organisms, which is put into action by exterior influences" (whatever that may mean); and in order to justify their refusal of the explanation given by other experimenters, they declare that the experiments by the latter were not performed under the same conditions—that is to say, that while the application of the medicines at a distance was practised by them in subjects in a state of lethargy or somnambulism, the subjects of MM. Bourru and Burot were in a wakeful condition.

Whatever may be the value of their explanations, Dr. Voisin affirms that from his own observations he finds that medicines hermetically closed in a vessel act by suggestion and auto-suggestion, and that the memory is acute in hypnotic sleep. Thanks to this state of the memory, one can explain facts which till now have been inexplicable. Moreover, he adds that the cases which have come under his notice equally demonstrate that by hypnotic suggestion one succeeds in suppressing attacks of hystero-epilepsy and vomiting. A young woman who had had these attacks daily, and went through this form of treatment, remained six months without presenting any of the symptoms of the above morbid conditions, and left the hospital apparently cured.

A short time ago Dr. Chouppe read a paper before the Société de Biologie on the good results he obtained with antipyrine to combat uterine colic. At the meeting of last week the author read a paper on the efficacy of this drug in a case that lately came under his notice of extremely painful contractions of the uterus, provoked by the action of the ergot of rye, which was administered to combat hemorrhages caused by a uterine myoma. Antipyrine administered by an enema, in a dose of two grammes, relieved the pain in twenty minutes. In subsequent attacks antipyrine, given a quarter of an hour before the ergot, prevented the occurrence of the pains, without in any way diminishing the intensity of the uterine contractions. This latter point is of the utmost importance, as it demonstrates the superiority of antipyrine over the preparations of opium in similar cases, whether in obstetrics or gynecology.

CHLORATE OF POTASSIUM AND TINCTURE OF IRON IN SORE THROAT.

To the Editor of The Medical Record.

Sir: I trust that you will not let pass, as a final condemnation, the recent editorial notice concerning the value of the old-fashioned mixture of "chlorate of potash" and "tincture of iron" as a remedial gargle in sore throats, whether diphtheritic, putrid, or simple, without first considering its value from two standpoints.

First, *clinically*, I would venture to state that ninety-five per cent. of all physicians will attest its well-earned reputation in their practice; and

Second, *chemically* (and it is here that I wish to call the attention of your readers to its value), it is not generally understood that the resulting mixture consists of a solution of chlorine (Cl_2), euchlorine (Cl_2O_4), potassium chloride (KCl), and ferric chloride (Fe_2Cl_6). On the value of free chlorine it is unnecessary to dwell. Euchlorine (Cl_2O_4) most readily splits up into (Cl_2+ $(O_2)_2$) chlorine and nascent oxygen, which also are most effective disinfectants and antiseptics. The chemistry of the reaction, once understood, is simply that of hydrochloric acid upon the chlorate, the oxygen of the chlorate "burning up" the hydrogen of the hydrochloric acid after the following reaction:

$$2\ KClO_3+(HCl)_4=(KCl)_2+Cl_2+Cl_2O_4+H_2O-$$

"Tincture of iron" always contains free HCl, and when HCl comes in contact with $KClO_3$, the above reaction takes place, *quickly* if concentrated, *slowly* if weak solutions are employed. In practice, such liberation (*i.e.*, a more efficient mixture) is best accomplished by ordering the tincture to be added to the dry chlorate and then diluted to the strength required. In fact, the patient does not receive the chlorate, but the chloride of kalium, the former being decomposed to form *the best practical* antiseptics and disinfectants known; while, unlike the horde of others (bichloride, carbolic or salicylic acid, eucalyptol, etc.), it possesses no poisonous qualities.

New Instruments.

A NEW INSTRUMENT FOR THE REMOVAL OF THE PHARYNGEAL TONSIL.[1]

By H. Gradle, M.D.,

Chicago, Ill.

Some months ago I spoke to the Society at length about the importance of hypertrophy of the pharyngeal tonsil—the so-called adenoid vegetations at the roof of the pharynx.

I then dwelt on the danger both to the ear and to the upper air-passages produced by this trouble. By following some of my cases for a longer period of time, it has seemed likely to me that, in some exceptional instances, even more serious disturbances to the health result from enlargement of the pharyngeal tonsil. I know now of at least five children operated on by me for this

trouble during the last year and a half, all of whom had been puny up to the time of the operation without being really sick. Since the operation these children have gained in flesh, vigor, and appetite, in such a manner that I am inclined to make the former pharyngeal disease responsible for their feeble health.

I have pointed out to the Society at a previous meeting that the operation of removing the pharyngeal tonsil, while neither dangerous nor difficult, nor very painful, was anything but elegant. For with the various forms of curettes which I had hitherto used, the vegetations were apt to slip from the grasp of the instrument, thereby necessitating a number of attempts, and sometimes a number of sittings, before the pharyngeal space was cleared. I have since obtained more experience in the galvano caustic treatment of the enlargement, and would rank this method far inferior to that by cutting instruments on account of the greater soreness produced by the burning, as well as the possibility of suppuration of the middle ear.

The instrument which I show you to-night I have found the most satisfactory of any method yet employed. It consists of a stout pair of scissor-blades, with prolonged handles bent out of the way, while the cutting ends of the blades turn up, so as to be placed behind and above the soft palate. These ends are fenestrated triangles, with the base up, thirteen millimetres wide, and twenty millimetres high. They apply themselves to the lateral walls of the pharynx when opened, while the cutting blades at their upper border snip off all prominences

[1] Demonstrated before the Chicago Medical Society, July 18, 1887.

from the roof of the pharynx when they come together. The couple of springs on the outside of the fenestrated ends serve as guards to catch any detached pieces, and prevent their falling into the larynx. With reasonable care I have found it impossible to wound any part of the naso-pharyngeal cavity with this instrument. The operation can be quickly done, and with a little tolerance on the part of the patient it can be completed in one sitting. The instrument has been neatly put up for me by Messrs. Sharp & Smith, of Chicago.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 27 to December 3, 1887.

So much of S. O. 235, A. G. O., October 8, 1887, as relieves Lieutenant-Colonel CHARLES T. ALEXANDER, Surgeon, from duty at St. Louis, Mo., and directs him to report for duty at Fort Meade, Dak., is amended so as to take effect January 1, 1888. S. O. 274, A. G. O., November 25, 1887.

BIRMINGHAM, H. P., Captain and Assistant Surgeon. The leave of absence granted by order No. 52, Fort Myer, Va., November 24th, is extended twenty-three days. S. O. 255, Division of the Atlantic, November 28, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 3, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	15	2
Scarlet fever	129	12
Cerebro-spinal meningitis	0	0
Measles	42	6
Diphtheria	198	58
Small-pox	1	1
Yellow fever	0	0
Cholera	0	0

MELANCHOLIA AFTER URETHROTOMY.—Dr. Edgar Kurz reports, in *Memorabilien* of August 5, 1887, two cases in which internal urethrotomy was followed by temporary melancholia. The operation was performed without accident, and resulted in a cure of the stricture in each instance. The melancholia was noticed shortly after the operation, but disappeared completely within a few weeks. The author states that a colleague related to him a similar case that he had observed in his own practice.

CHLORIDE OF ZINC IN HYDROCELE.—Dr. Lerond recommends, very highly, injections of a ten per cent. solution of chloride of zinc, with or without previous evacuation of the fluid, for the cure of hydrocele ("Thèse de Paris," 1887). The operation is a very simple one, devoid of danger, and usually effects a speedy cure, seldom being followed by a relapse.

A CHINESE REMEDY FOR CROUP.—Collect from old walls seven nests of large-sized spiders, two of which, at least, should contain live spiders. Make them into a paste with thirty grains of alum previously dissolved. Then, after it is well mixed, reduce the paste to ashes and apply it hot to the throat. This will effect an instantaneous cure of the malady, no matter how severe it may be.

DEATH OF AN AGED PHYSICIAN.—Dr. Neklewitsch, of Loske, in Poland, has lately died at the age of one hundred and nine years, having, a quarter of an hour before his death, seen and prescribed for a patient. Sixteen years ago he had a paralytic stroke affecting both his feet, so that he has since that time been obliged to confine his professional advice to the consulting-room.—*The Lancet.*

NO PHYSICIAN WANTED.—Kotelnich, in Russia, is a thrifty town, or else a very healthful one. The town council has recently voted to dispense with the services of its city physician, thinking that a Feldsherr and a midwife are sufficient for the needs of its poor.

REFLEX CONVULSIONS FROM HERNIA.—Dr. Gonzalez Alvarez reports, in the *Archivos de Medicina y Cirugía de los Niños*, an interesting case of convulsions occurring in a child eleven months of age. A diagnosis had been made of meningitis, but as no other symptoms of this disease were present, the author was inclined to regard the spasms as reflex in nature. The child was stripped, and it was then seen that he was suffering from strangulated inguinal hernia. After considerable difficulty the hernia was reduced by taxis, and a truss was applied. The convulsions ceased at once, and there was no return.

STATISTICS OF TRACHEOTOMY.—At the recent meeting of the Italian Surgical Society, in Genoa, Dr. Cabelli presented some statistics of tracheotomy which he had collected. In the first series of 132 cases there were 50 deaths and 82 recoveries. In a second series of 18 cases there were 5 deaths and 13 recoveries. In the first series, therefore, the recoveries numbered 62.2 per cent., and in the second 72.3 per cent.

WAFERS FOR ADMINISTRATION OF BAD-TASTING FLUIDS.—Mix bad-tasting fluids, such as turpentine, balsam copaiba, ichthyol, etc., with sugar, coffee-powder, or flour, and then inclose and administer in wafers.

CASTOR-OIL is easily given in foaming beer. It seldom causes vomiting when given in that way. Glycerine, combined with castor-oil, according to Soper, increases the purgative power of the oil. Wood's formula is: Ol. ricini, glycerini, āā ℥j.; ol. menth. piperit., gtts. ij.

RECTAL INJECTIONS IN CYSTITIS AND ENLARGED PROSTATE.—Dr. Vercoe calls attention to the value of rectal injections of hot water in cases of enlarged prostate and cystitis. He irrigates the prostate and base of the bladder with hot water, applied directly to the parts through a large, double-eyed catheter passed per anum.—*The Medical Age.*

LEPROSY INCREASING.—According to Bésnier, leprosy is spreading rapidly. Since the extension of the French colonial possessions, soldiers, sailors, traders, and missionaries have fallen victims to it in large numbers. Bésnier therefore exhorts physicians in all countries to study the fell disease, in order to find means of counteracting its ravages, for it has active focuses of infection in every part of the globe.

THE TREATMENT OF FLATULENT DYSPEPSIA.—Dr. Huchard warmly recommends: ℞. Salicylate of bismuth, parts ij.; calcined magnesia, parts ij.; powdered willow-charcoal, parts iij.; oil of anise, part j. Of this powder a small teaspoonful may be taken an hour or a half-hour before a meal. When gastralgia is present he recommends the following: ℞. Syrup of peppermint, parts ccl.; hydrochloric acid, part j.; hydrochlorate of cocaine, parts j.-x.; of which a small glass may be taken after a meal.—*Revue Générale de Thérapeutique.*

MAN CONSUMES, in his threescore years and ten, eighty tons of liquid and solid food. This calculation is based on an average consumption of one hundred ounces a day.

A METHOD OF TREATMENT OF FIBROID TUMORS OF THE UTERUS BY STRONG CURRENTS OF ELECTRICITY BASED UPON EXACT DOSAGE.[1]

A MODIFICATION OF APOSTOLI'S METHOD.

BY FRANKLIN H. MARTIN, M.D.,

MEMBER CHICAGO GYNECOLOGICAL SOCIETY, PROFESSOR OF GYNECOLOGY IN CHICAGO POLYCLINIC.

By analysis of the several recognized methods of treatment of fibroid tumors of the uterus by electricity, I have been led to attribute the effects of the galvanic current to four principal actions :

1. Local effects of the poles.
2. Atrophic effects of the current.
3. Electrolytic action of the current.
4. Antineuralgic effect of the current.

Local effects of the poles.—In considering the Apostoli method we have dwelt at length upon this point. We have seen that the effect of a metal electrode upon the mucous membrane of the uterus, with a concentrated current passing through it and through the tissues in contact with it, is to produce a kind of cauterization ; that this effect is similar to that produced by an alkali if the pole is negative, and to that of an acid if the pole is positive. We find an explanation for this in the following fact : If into a solution of chloride of sodium or any other electrolyte we plunge the two electrodes of a galvanic apparatus, it will be found that there is a strong tendency for the acid radicals of the electrolyte, as it is broken up by the passing current of electricity, to gather around and attack the positive pole, and an equally strong tendency for the alkaline radicals to become liberated at the negative pole. It is just this effect that we get at the negative pole, or at the positive pole of our battery, when in the form of a metal electrode it is brought in contact with the mucous membrane of the womb.

In order to produce electrolytic action enough in the region of a positive inter-uterine metal electrode to obtain the characteristic hardening and coagulation of the tissues in contact, by liberation of acid radicals sufficient to check hemorrhage, a certain concentration of current is imperative. In other words, a given density rather than amount of current is required.

Atrophic effects of the current.—Atrophic effect is the name I will take the liberty of giving to a peculiar influence that is often noticed after the use of electricity on fibroid growths, which I am unable to account for in any other way than as an effect upon the trophic nerves upon which these tumors must depend for their nutrition. There are examples of rapid total disappearance of fibroids of considerable size after one or two applications of strong currents ; and examples of others that have continued to gradually atrophy for months after one application, but which have not entirely disappeared. This peculiar effect cannot be attributed to electrolysis, because electrolysis ceases to effect a diminution in size as soon as the *ions* set free by the process are absorbed ; which would not be likely to require more time than a very few hours. The local effect of the poles cannot account for the fact, because it has been observed where the poles had never come in contact with any part of the growth. It is well known, however, that peculiar irritations of motor or other nerve-trunks or their branches, which are supposed to contain inherently or in close association trophic influence, will oftentimes cause progressive or rapid atrophy of the tissues under their control. I believe that electricity, powerfully concentrated as it is in this treatment, in passing through these tissues has oftentimes some such destructive effect on these trophic nerves, or nerves which carry a trophic influence, and thereby cut off the powers of nutrition in the tissues.

Electrolytic action of the current.—Electrolysis is the well-known power of resolving compound bodies into their constituent elements by passing through them a current of electricity. . Electrolysis only occurs in that part of the body which is in a fluid state. While the galvanic current passing through a soft, living tissue has not an uninterrupted fluid medium, it has practically a fluid medium divided into innumerable little compartments, each one separated from the other by a thin wall of solid. During the passage of the current each of these particles of solids acts as a positive electrode on the fluid between it and the next solid particle in front, and as a negative electrode upon the fluid between it and the solid particle behind it. Each molecule of fluid in a conducting solid, therefore, in the line of galvanic current, may become electrolysized. It is found, also, in passing a galvanic current through a portion of the soft tissues of the body, that there is considerable tendency to cataphoric action. That occurs by a direct transferrence of the fluid particles through the little-permeable walls of solid in the direction of the negative pole of the battery. Thus we find the effect of electrolysis on a portion of the soft fresh tissue to be : (1) A separation of combined elements (more or less) into their constituent elements, and a rearrangement of the same. (2) A general movement of the elements in solution toward the negative pole of the battery.

Now, by a little ingenuity, can we not readily explain how absorption is promoted by the process of electrolysis when applied to living normal tissue? A moderate galvanic current is passed through a part, and the most susceptible molecules in the course of the current become broken into their original elements : (1) These elements immediately make a similar or different combination with neighboring elements of opposite electrical tendencies, making thereby new compounds which act as foreign particles; as foreign bodies they are promptly removed by the nearest absorbent. (2) Other elements, as they become free from their original molecules, make combinations with elements which are already leaving the tissues through some of their innumerable minute vascular or absorbent canals. (3) Many, in the form of gas, pour into the atmosphere beneath and surrounding the electrodes. (4) Others attack the electrodes and are disposed of in the form of deposit on their surfaces. (5) The current by its cataphoric action, that is, by its direct transferrence of fluid particles in the direction of the negative pole, produces an engorgement of the tissues at the negative side of the part acted upon. The absorbents in that portion of the tissue will promptly make an effort to establish an equilibrium, and by a direct action of endosmosis they are filled and the excess is carried away in their current.

This is what I believe takes place in the substance of a fibroid tumor when a more or less concentrated cur-

[1] Abstract of a paper read before the Section of Gynecology at the Ninth International Medical Congress.

rent of electricity is forced through it. At the active pole we are certain that electrolysis takes place, because an active bubbling of gas through the secretions surrounding the electrode is often observed. The foot of the rapid diminution in the size of the tumor in all its parts during the progress of active treatment, and its ordinary increase in many cases when treatment is suspended, forces one to attribute a portion of the beneficial effect to the absorption rendered possible by electrolysis.

The antineuralgic effect of the current.—There is no symptom of fibroid tumors of the uterus that yields more readily to electricity than the severe pain that so often accompanies them. While in an experience of over three years with these distressing maladies I have never seen a case in which the severe neuralgias have not succumbed early, I must confess I have not been able to discover any rational explanation for the fact.

Exact dosage.—In the treatment of fibroid tumors that I am about to describe I have, by the adoption of peculiar electrodes and by the control of certain principles that I have already hinted at, been able to lay down a more exact system of dosage than has heretofore been in vogue, in which all the effects of electricity above enumerated can be obtained without the necessity of causing the slightest pain to the most sensitive patient.

Experimenting, I have found that a current of 25 milliampères, traversing a positive platinum electrode of one square centimètre surface pressed firmly against the mucous membrane of an hypertrophied cervix, the circuit being completed by a large abdominal electrode, will produce a dry condensed condition of tissues beneath the surface of the plate in five minutes.

This surface can be penetrated with a lance to the depth of a millimètre and a half without producing the slightest tendency to hemorrhage, and the tissues are

Fig. 1.

denser than normal, still some distance farther below the surface. Granting that the condition obtained in this experiment is what is sought in cases of hemorrhagic fibroids throughout the whole surface of the mucous membrane of the uterus, in order to prevent subsequent hemorrhages, we can recognize a basis in the experiment from which we can construct a table of exact dosage, so far as the treatment of the hemorrhagic element is concerned. For by carrying our experiment still further it is found that a current of 50 milliampères is required, or just double the strength of the current required in the former experiment, to produce in the same time the same effect when the surface-area is just double, or two square centimètres. If, therefore, for example, we have a uterine canal that is 10 centimètres in depth, and the electrode fitting the canal has a surface of one square centimètre to each centimètre in length, we would have ten square centimètres of active surface in contact with the tissues; this, therefore, figured upon the same basis, would call for a current of 250 milliampères for five minutes in order to get the characteristic effects necessary to check hemorrhage from the whole surface. Or, the uterine canal that would require an Apostoli electrode 20 centimètres in length, and this depth is not infrequently met with, would require a current, if the electrode was 4 mm. in diameter, and if equal conduction took place from its entire surface, of over 600-milliampère strength. This strength of current would not be tolerated in a large number of cases, and if it were, there is no means of being certain that the sound comes in accurate contact with the mucous membrane in its entire extent. There is some doubt, too, that a surface so large, even if it were in accurate contact, would conduct equally from its entire area; the consequences, therefore, in this case would be excessive cauterization and subsequent suppuration of portions of the mucous membrane, and little effect, if any, on other portions. It is this uncertainty of result and painfulness of application that I have succeeded in doing away with. This is accomplished by adopting a means by which the whole mucous membrane of a hemorrhagic uterus can be successfully treated in a number of *séances* by attacking successively different portions of it until the whole area has been covered.

To accomplish this I have had constructed peculiar internal electrodes (Fig. 1). I have confined myself so far to two sizes—one with an active surface of two square centimètres, the other of four square centimètres; the first to be worked with a current of 50 milliampères, the

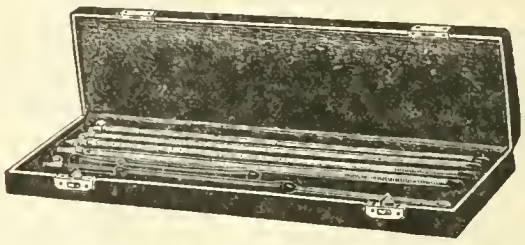

Fig. 2.

second with a current of 100 milliampères. The metal that constitutes the active surface of these electrodes is platinum wire in spiral (Fig. 5, *b*) wound over soft copper, wire of the required diameter. This portion of the electrode is connected with the handle of the electrode where it receives its attachment to the battery by means of an extension of the flexible copper wire or core incased in a soft rubber insulator. This insulated portion with its insulator is of the same diameter as the platinum part of the sound, and is therefore small enough to enter the uterine canal. Upon the distal end of the platinum portion is a screw-attachment, upon which a small, hard rubber tip, about two millimètres in length, is attached. This tip is bulbous, and from its shape and material will follow the canal readily. One may at once see that these electrodes can be made of any required diameter to suit the exigencies of the particular case in hand, this depending, of course, upon the size and permeability of the uterine canal. I have confined myself thus far in my work to two diameters. They are of 3 and 5 millimètres, and are called respectively No. 3 and No. 5. Other sizes can be ordered of the instrument-makers on the same basis of nomenclature—the diameter required stated

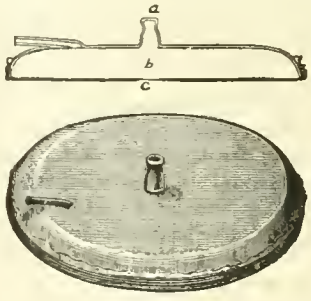

Fig. 3.

in millimètres. Of each of these two diameters, as I have stated, I have had constructed two electrodes—one of 4 sq. ctm. metal surface, the other of 2 sq. ctm. metal surface. Of course the length these active surfaces occupy on the different electrodes depends upon the diameter of the particular electrode. If it is 3 millimètres in diameter the 4 sq. ctm. will occupy about 45 mm. in length of the instrument; if it is 5 mm. diameter the same surface, 4 sq. ctm., will occupy but about 26 mm. in length of the instrument. In ordering, then, an electrode from the instrument-maker, the diameter of the instrument and the strength of current to be used with it should be stated. Thus if an electrode is required of 3 millimètres in diameter, and the current to be used with it is 100 milliampères, simply order a $\frac{3}{100}$ electrode; if a 100 milliampère current is too high, order a $\frac{3}{50}$, which will indicate an electrode 3 mm. in diameter with a surface which will require, to check hemorrhage, a 50-

mialliampère current. Each set of electrodes has a rubber shield or muff (Fig. 5, *a*) that slides loosely upon the extra-uterine portion of the instrument when inserted, which acts the double purpose of an insulator for the vaginal portion and as an indicator of the depth the electrode occupies the uterine canal, the proximal or external portion of the staff of the instruments being graduated into centimètres for this purpose.

The instrument-makers have kindly arranged a compact case of these electrodes (Fig. 2). It contains all the electrodes ordinarily demanded for this work—two of 3-millimètre diameter and two of 5-millimètre diameter; one of each for a 50-milliampère current, and one of each demanding a 100-milliampère current.

The surface-electrode (Fig. 3) is also one of my own device, and has been successfully used by a number of operators. Over the concavity of a concave disk (*a*) of soft metal of appropriate dimensions is loosely stretched an animal membrane (*c*) which is fastened to its circumference securely enough to render the interspace watertight. Between the concavity of the disk and the membrane is left a space (*b*) one and one-half inch in thickness, which is filled with warm water or warm solution of salt. The electrode is filled through a stopper on the surface of the metal; the connections are also made from this surface.

This electrode is applied to the surface of the body so that its membrane-surface is in contact with the skin, and was devised with an eye to cleanliness, to take the place of the potter's-clay electrode used for the same purpose by Dr. Apostoli. It adapts itself accurately to all irregularities, covers a large surface (400 to 800 square centimètres), and causes a diffusion of the current so perfectly that a very powerful current can be employed with it without producing the slightest pain.

Means of generating a current.—The current of electricity used for these operations should be one of high electro-motive force and small ampère strength. It should be very uniform and without interruption. Any means of generating electricity that will be practicable, and at the same time answer the above requirements, will be suitable for the purpose. I have employed for most of my work a battery composed of ordinary crowfoot gravity-cells, sufficient in number to obtain an electro-motive force of 150 volts. The Leclanché battery is practicable for this work, and is the one employed by Dr. Apostoli; it is one of the best. Batteries of the best, however, I think will soon be replaced by the dynamo.

As long as electricity in medicine and surgery was confined to faradization and galvanization with small currents, batteries were the most economical means of obtaining the desired effects; but now, with our growing knowledge of the importance of the galvano-cautery and the possibilities of the electrolytic current of high electro-motive force, we are forced to acknowledge the impracticability of the batteries and the necessity of obtaining a more economical and durable means of accomplishing the same end.

In the commercial world this same problem was met with, confronted, and at last solved by the perfection of the dynamo. I would not hesitate to predict as brilliant strides for medical and surgical electricity from the adoption of the dynamo as was noticed in the commercial world with the adoption of the same means.

The machine (Fig. 4) which I have the pleasure to bring to the notice of the profession here, and which I have had constructed to take the place of all batteries, is a dynamo that will generate electricity sufficient for all purposes that are at present demanded by medicine or surgery. If the field of medical and surgical electricity in further development requires more energy, it can find a means to that end by simply enlarging this apparatus in proportion to its demands.

The capabilities of the machine can be brought out by one-third actual horse-power force.

The machine differs from the ordinary dynamo for electric-light purposes in (1) being constructed so as to be capable of generating two distinct currents; (2) each of the currents can be increased in gradual gradation from zero to its full power without altering the speed of the machine; (3) both varieties of current can be utilized at the same time in different work, or at the will of the operator either one can be used; (4) the machine possesses an automatic safety-device by which the current is not allowed to reach a strength that can do harm to the patient or the machine itself.

The two currents generated by the machine are identical with those generated by a cautery battery of large

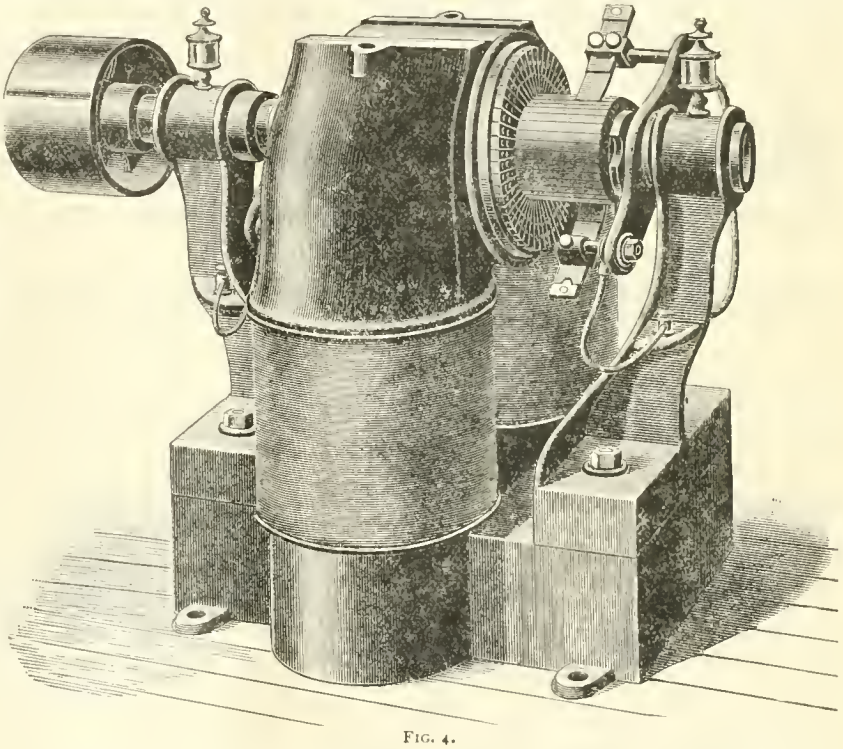

Fig. 4.

cells and large surface, and with that generated by a large number of small cells arranged in series, and are designated respectively the cautery current and the electrolytic current. The maximum strength of the cautery current is 40 ampères, with a possible electro motive force of 2 volts. The maximum strength of the electrolytic current is 1 ampère, with an electro-motive force of 200 volts. Thus this little machine will generate a cautery current that is steady, uniform, and enduring, that will accomplish the work of our largest cautery batteries made for office purposes. It will, at the same time it is accomplishing its maximum cautery work (or alone), generate a totally different current that will furnish energy sufficient to run at least one of Edison's sixteen-candle incandescent lights, or that will accomplish any work that can be accomplished by a battery of 150 Leclanché cells. This latter current also possesses the following advantage over cell-battery currents. In case of the cells the current must be turned on one volt at a time, whereas with this machine it can be evenly increased or diminished in less gradations than the hundredth of a volt, thereby not exciting the patient in the least while giving the full benefit of a perfectly smooth and uniform galvanic current of any required intensity.

These results are obtained without the use of a rheostat or resistance. It is also especially adapted for operating the induction coil for faradic currents, giving a very delicate adjustment of the current in the primary.

The medical dynamo was devised for me by Elmer A. Sperry, of Chicago, a practical electrician of large experience, and was manufactured by the McIntosh Galvanic and Faradic Co., of Chicago. It is a beautiful little machine, and can be operated by gas-engine, electric-motor, or any other convenient power.

Variations of operation.—In describing in detail this method of operating I wish to recognize two varieties:

1. *Positive intra uterine galvanism.*
2. *Negative intra-uterine galvanism.*

The variety positive intra-uterine galvanism corresponds to Apostoli's galvano-caustique positive, the second to his galvano-caustique negative. I take the liberty of making this change of nomenclature because I do not believe that a true caustic effect is what we should seek to obtain. With the negative pole we get free escape of liquid and hydrogen gas from the surface beneath the electrode, from powerful electrolytic action, and a condition is produced that will stimulate rapid absorption, but it should not be carried to the extent of local destruction. With the positive pole we get active coagulation of the albuminous particles of the tumor by action of the acid radicals produced by rapid electrolysis. The concentration of the current, however, should not be so great as to cause actual destruction of the tissues.

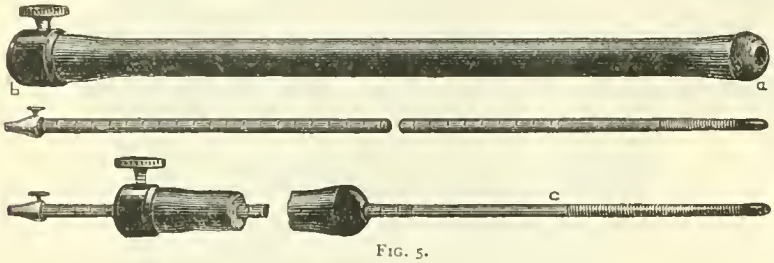

Fig. 5.

Modus operandi: Positive intra-uterine galvanism.—The first variety of operation, positive intra-uterine galvanism, is indicated in that large majority of fibroid tumors that presents a history of excessive hemorrhage. This condition is present in a large variety of cases. It matters not if it be the small submucous, the larger interstitial, the large subperitoneal, or even the large base-pedunculated tumor, the indications for treatment are the same, if there is a flow of blood from the mucous membrane of the uterus. The uterus may also vary in depth from seven to twenty centimètres without changing the indication for treatment, or lessening the chances of success.

The operator proceeds, after the patient has been instructed to assume a convenient position, to discover the whereabouts of the cervix and endeavor to ascertain, by means of a uterine sound, the depth and direction of the canal. This is the most difficult part of the operation, oftentimes, because of the extreme distortion of the canal. I have been obliged in a number of cases to postpone treatment from day to day for a number of days, because of being unable properly to adjust the electrode in the uterine canal. I have yet, however, to find a case in which, after more or less persistence, I have not been rewarded finally by being able to traverse the canal with the flexible electrodes that I have described; after once accomplishing an entrance, and learning the peculiarities of the canal, the future introduction of the electrode becomes an easy matter. At the first treatment the electrode of proper diameter should be selected, and inserted to the bottom of the uterus and connected with the positive pole of the battery. Upon the surface of the body, attached to the negative pole, should be placed the passive membranous electrode (Fig. 3), in a position that will cause the electricity to traverse the largest mass of the fibroid. After the connections have been well examined, in order to insure their security, and the insulating muff (Fig. 5, *a*) has been slid up to the cervix and fastened, the current from the generator is turned on very gradually until a current of 50 milliampères has been reached, if the active surface is 2 sq. ctm., and 100 milliampères if the active surface of the electrode is 4 sq. ctm. The current is then allowed to pass for five minutes, when it is gradually reduced, until it is entirely turned off. The electrodes are then carefully removed, and the application is finished. This first operation produces a coagulation of two or four centimètres, according to whether the active surface of the electrode occupied two or four centimètres of the distal end of the uterine canal. When the internal electrode is withdrawn, the depth of the uterine canal is noted or indicated by the position of the muff, and this fact, together with the diameter of the electrode, is carefully noted in the records of the case for that day. At the next application, which can usually be as soon as the next day, before introducing the same electrode the intra-uterine portion of the instrument should be shortened, by setting the rubber muff or gauge just the number of millimètres nearer the distal end that the active surface of the electrode measures millimètres in length. Upon introducing the electrode into the uterine canal now, as shortened by the position of the muff, the active portion of the instrument will reach exactly to the point that was acted upon at the previous application. It can readily be seen that in this second operation another portion of the canal has been treated. This same procedure is continued every day, with a change of the gauge every time, until the whole canal has received the action of the metal portion of the electrode. This line of treatment (the galvano-positive, should be thoroughly carried out the four or five days immediately preceding the regular time for menstruation to appear. If the patient exhibits an indifference to the effect of a 50-milliampère current, the work can be done in half the time, and just as well, by substituting the electrode of 4 sq. ctm. in surface with the 100-milliampère current.

As I have intimated, the positive intra-uterine galvanism should be employed the week preceding the regular menstrual flow. If, as in a large number of these cases, the hemorrhage has lost its regular periodicity or the hemorrhage is continuous, the judgment of the operator should guide him in selecting a time when the hemorrhage is not present, or when there is the minimum amount. If, however, the hemorrhage is continuous, the treatment must be given during the flow.

Negative intra-uterine galvanism.—The second operation, the negative intra-uterine galvanism, can usually be performed with the 100-milliampère current, unless the patient is particularly susceptible to the effects of electricity. In this operation the intra-uterine electrode is carefully introduced to the bottom of the canal, as in the first operation, but is connected with the negative pole of the battery instead of the positive. The surface-electrode is properly arranged, and, after all connections are rendered secure, a current of 100 milliampères is gradually turned on and allowed to work for five minutes. Of course, if the surface-effects of a 100-milliampère current is at all disagreeable, the electrode requiring the 50-milliampère current should be substituted and the 50-milliampère current employed. The same procedure should be adopted in regard to changing the position of the active surface of the electrode, in order to accomplish the characteristic action on all portions of the canal.

The effect of this operation is to produce rapid reduction in the size of the growth, and it should be employed in the early days of the month following a menstrual period, and should always be followed later in the month by the positive intra-uterine galvanism in order to prevent the ex-

cessive hemorrhages that would otherwise occur at the following menstruation. This latter operation can readily be tolerated every second day, and very frequently every day.

In the two simple procedures here presented, we have a safe, painless, accurate, and rational method of treating fibroid tumors of the uterus by Apostoli's method. By this method all the beneficial effects of electricity can be obtained, without in the least exposing our patients to any of the possible evils that we are able to discern in other methods. It has been shown that the maximum current advised, 100 milliampères, by proper condensation will do exactly the same work locally, and with more certainty, than currents of much higher intensity that are employed without taking into accurate account the extent of the active surface of the electrode. The atrophic effect of the current is more liable to be obtained when there is a systematic condensation of the current at successive applications to the whole internal surface of the uterus, and therefore through all portions of the tumor at different times, than when a much stronger current is employed indifferently diffused through all portions. For the same reason the electrolytic effect of the current becomes more certain and effectual when the current is concentrated than when it is indifferently diffused. The antineuralgic effect of the current is obtained almost invariably with this method, although this particular procedure offers no advantages in this respect over any other.

In recommending this gradual process of treating these difficulties, I do not do so because of any great advantage that I expect to obtain from lessening the strength on account of the pain, but because of the more accurate application and the more definite results that are obtained with a smaller surface of concentration. I have had a large experience with Apostoli's method, and have employed much stronger currents than he has advised, without producing excessive pain, but I found it was not always possible, even when the greatest precautions were taken, to avoid uneven work.

In conclusion, the principal advantages of this method can be summarized under six headings:

1. It is entirely free from danger.
2. It is absolutely painless.
3. It invariably checks excessive hemorrhages.
4. It rapidly reduces the size of the tumors.
5. It stops neuralgic pains.
6. It is a system of treatment of fibroid tumors by electricity, based upon principles which make exact dosage possible.

163 State Street.

Luminous Micro-organisms.—Dr. Tilanus, who has been working in Professor Forster's laboratory in Amsterdam, on culture-preparations of luminous micro-organisms, has published an account of his researches. He prepared a flat culture from luminous mucus, obtained from the exterior of fish, with fish-broth peptone jelly, to which two per cent. of common salt had been added as a medium. This became speckled with numerous cultures, some of the jelly, but not the greater part, becoming liquefied. In the dark this flat culture emitted a distinct light, and appeared as if strewn with stars; from this a stripe-culture was prepared, and, after successive preparations had been made, Dr. Tilanus believed he had obtained a pure culture of the phosphorescent organisms. They stained well with methyl violet or methylene blue. With a power of 1,000 diameters they appeared of an ovoid form, with numerous clear, colorless points. A low temperature was found to be most suitable for these cultures. Besides fish-broth, potatoes sprinkled with salt were found to serve as a medium, but blood-serum gave very unsatisfactory results.—*British Medical Journal.*

HYPERTROPHY OF THE TONSIL OF THE TONGUE, WITH HISTORY OF CASES.[1]

By J. W. GLEITSMANN, M.D.,

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, NEW YORK POLYCLINIC.

The affection which forms the subject of my paper does not receive the attention it well deserves. It is often an unrecognized source of a variety of complaints, which are only successfully relieved by treatment of the glandular hypertrophy in question. Although numerous researches have revealed the true pathological character and the microscopic constituents of the diseased tissue, very few writers have given a description of its clinical features, and the majority of publications confine themselves to an enumeration of one or the other prominent symptom of the individual case. As I had occasion to treat a number of cases during this year, I beg to submit the result of my observations to the meeting.

The tonsil of the tongue consists of a group of follicular glands, similar to those of the faucial and pharyngeal tonsil, and forms the connecting-link of the great lymphatic ring of the pharynx. Commencing at the pharyngeal tonsil, this ring extends to the orifice of the Eustachian tube, then turning downward along the posterior surface of the soft palate to the faucial tonsil, it reaches the base of the tongue, and returns in the same order. The ring has an almost vertical position, and is characterized by an accumulation of follicular glands in several places. The glands are found in two different forms; in some localities they appear in aggregated, in others in disseminated form. When they are aggregated they represent a circumscribed mass, which is commonly called a tonsil. Other attributes of a tonsil are a dense, diffuse infiltration of the connective tissue with lymph-cells, and the prevalence of follicular, or, as Cohen better calls them, saccular glands. While these three conditions exist in the faucial and pharyngeal tonsil, the tonsil of the Eustachian tube and of the tongue have not the circumscribed form, and contain the follicular glands in the disseminated state. But cases are not rare in which the accumulation of these glands assumes a formidable, well-defined shape, and the Eustachian tonsil has been known as such for some time. The name, tonsil of the tongue, has, as I think, been used with perfect propriety by some writers for a similar condition at the base of this organ. Without further entering into the histology of these formations, it is well to remember that they are not glands in the common sense. They have no excretory duct nor outlet, are closed bodies, and by their function belong to the lymphatic system. They are of the size of a lentil, are loosely embedded in the submucous tissue, and their hilus is covered by a thin mucous membrane. Their sac contains a varying number of follicles, closely resembling those of Peyer's glands of the intestines.

According to the researches of Swain, who has given so far the best description of our subject, the existence of these glands at the base of the tongue is a normal condition. They are located between the papillæ circumvallatæ and the epiglottis, often encroaching on both, and they generally appear at the period of puberty. In the hypertrophic state their growth is uniform, and all the parts of the gland take part in it. The whole gland is enlarged twice its size, and more; the follicles themselves become considerably larger. This hyperplasia resembles closely the condition observed in chronic hypertrophy of the faucial tonsil, and is another instance of similarity of these two organs.

I am unable to give a satisfactory explanation of the causes productive of this disease. My patients, as well as those of others, had attained the age of puberty, the majority of them being between twenty and forty years of age. Aside from the knowledge of an ailment which

[1] Read before the Section on Laryngology and Rhinology of the New York Academy of Medicine, November 22, 1887.

made them seek medical aid, they were unaware of the condition existing in their throat, and greatly surprised when informed of the nature of the trouble. In my opinion the same agencies are most likely at work which bring on hypertrophy of the faucial tonsil, with the difference of their appearance at a later age of the patient.

The symptoms we observe in patients are manifold, but mainly due to the mechanical irritation brought on by the hypertrophic glands. Some of these symptoms have already been described, and we are indebted to two members of our Section for having pointed out two of the most important ones. Dr. Rice has given a very graphic illustration how a severe spasmodic cough can be completely relieved by proper reduction of these glands, and Dr. H. Curtis related his experience of their influence on the singing voice. Dr. Curtis was, as far as I know, the first to have drawn attention to these growths from a clinical stand-point. But besides these two symptoms we notice an array of others, and we shall now investigate them more fully. We hear the patients complain—1, of the sensation of a foreign body or of pressure in their throat; 2, of interference with their speaking or singing; 3, of pain when there is subacute inflammation of the glands; 4, of radiating pain; 5, of cough; 6, of asthmatic attacks.

The first symptom I found to be the most constant one. The existence of a mass of hypertrophic tissue at the base of the tongue creates the feeling of the presence of a foreign body, and the patient endeavors to remove it by swallowing. This is the cause of the so-called empty-swallowing, which is often incessantly repeated with but temporary relief. This sensation is experienced less during eating, and generally only when no food is taken. It is next to impossible to enumerate all the foreign substances which the patients believe to be present. All imaginable things, from a leaden ball to a hair, are given as the source of the evil. In this connection it will not be amiss to state that quite a number of cases of globus hystericus can be satisfactorily explained by the hypertrophy of these glands, and cured by their destruction. The sensation of pressure in the throat is in the same manner due to the enlarged glands, and aggravated when there is actual contact between the epiglottis and the tongue. Nervous patients become more and more irritated by the foreign body and the pressure they feel in their throat, and very often experience great suffering.

The interference with speech and song is probably the most interesting symptom of our disease. In some cases the patients only tire out very soon when using their voice, in others the voice is entirely lost. There are instances known where the voice is good one day, bad the next, and where it breaks suddenly during singing. Professionals also say that they are no longer able to find the right key, or that the voice has lost a great deal of clearness and metal.

The only complaint of other patients is that they have pain while talking, without being hoarse. I refer now only to patients who have no concomitant disease, as, for instance, catarrhal laryngitis, granular pharyngitis, or to such whose ailment continued unabated after hypertrophic faucial tonsils, or granulations of the pharynx, or the like had been effectively treated. If the hypertrophy of the glands is so great as to overlap the free border of the epiglottis, the explanation of their influence on the voice is easy. In this case the free movement of the epiglottis is seriously interfered with, and the constant exertion necessary to produce a sound creates a feeling of fatigue. If there is no impingement of the epiglottis and simple contact with the tongue, we have to remember that the position of the tongue and larynx change with each articulation. When the follicular glands are swollen the epiglottis is exposed to friction with each movement, its nerves become irritated, and this irritation is transmitted to the muscles and nerves of the larynx. In some cases the fatigue of voice can be traced to deficient innervation.

Although the enlarged condition of the follicular glands is decidedly a chronic process, subacute inflammation does sometimes occur. Patients who formerly complained only of discomfort in swallowing, or of pressure in their throat, suffer actual pain when an inflammatory exudation of fibrinous material into the follicles takes place. In a lady under observation, who only had the sensation of a foreign body in her throat, the glands were moderately enlarged without touching the epiglottis. After most of them had been reduced by the galvano-cautery she appeared one day suffering severe pain in her throat, which she considered due to a cold. On inspection numerous white spots, of the size of a pin's head, could be seen, covering the entire base of the tongue, and resembling closely the aspect we are wont to see in follicular tonsillitis. It took very persistent scraping with the sharp spoon, and repeated insertions of a fine galvano cautery point into the diseased follicles to make the inflammatory symptoms disappear.

Radiating pains toward other parts of the body I noticed only in one patient. She complained of shooting pains toward each side of the throat, extending upward to the ears. Destruction of the hypertrophic glands gave prompt and complete relief. Cases are described in which patients felt pain between the shoulder-blades, in the larynx, trachea, also in the stomach.

Quite a number of patients suffer from cough, which is observed in two different forms. It is either a violent, spasmodic, almost incessant, or a hacking cough, appearing at shorter or longer intervals. The spasmodic form, as a rule, occurs when the hypertrophic glands encroach upon the epiglottis, and is less frequent than the hacking cough. The latter often gives rise to great anxiety on the part of the patient and his relatives, as they fear it to be a symptom of developing phthisis of the lungs. In the cases under my observation this form of cough was present when there was merely contact between the glands and the epiglottis, and it is most probably due to the friction of the tongue and epiglottis against each other during their movements.

Finally, the last symptom to be mentioned are asthmatic attacks. Although I have not seen any case myself, Heyman and Seifert describe attacks of dyspnœa, resembling asthma, in patients with enlarged follicular glands. So far the observations are very few in number, but it will be advisable, in the future, to examine closely the base of the tongue before we consider a case of asthma as one of purely nervous origin.

To illustrate more fully the symptoms alluded to, and their great variety, I append the histories of a few patients:

Case I.—Mrs. R——, married, aged twenty-nine, professional singer. She had been performing in concerts and opera on the Continent and in this country. Her voice had never failed her, and although subjecting it sometimes to an unusual strain, she never felt any discomfort afterward. About one year ago she began to feel easily fatigued when singing any length of time, and when continuing she could only do so by great exertion. Of late she noticed, on several occasions, that in making such an exertion she would lose control over her voice, and it broke completely. She also complained of a slight sensation of pressure in her throat. The patient was otherwise perfectly healthy, but very downcast on account of the fear of never regaining her full vocal power.

At the examination the whole upper air-tract was found to be normal, except a few patches of granular tissue in the pharynx, and moderately enlarged follicular glands, which, however, did not interfere with the movements of the epiglottis. Not fully appreciating the importance of this condition at the time, I was greatly surprised when, after destruction of the granulations, but slight improvement was obtained. Permanent benefit only resulted from a methodic, and, in this case, especially persistent,

treatment of the follicular hypertrophy. The means adopted in this and other instances I shall summarize when speaking of the treatment.

Case II.—Mrs. G——, married, aged thirty-seven, complained of a dryness and burning in her throat for the past four weeks, obliging her to drink very often. She also has the sensation of a string lying on the back of her tongue, which she in vain tries to get rid of by frequent attempts at deglutition. When she takes food this feeling is less, but after she has swallowed a mouthful some particles of food seem to remain on the tongue, and the fruitless efforts at swallowing commence again. During the last week she was also greatly annoyed by pain in both ears, which, although of short duration and coming at long intervals, was nevertheless very acute and painful.

A minute inspection revealed nothing but the presence of a circumscribed mass of follicular glands right in the middle of the base of the tongue, slightly covering the edge of the epiglottis. Three applications with different agents gave complete relief.

Case III.—W——, male, aged twenty-seven, amateur singer; suffers since ten years from what he calls "catarrh;" which, however, did not materially affect his singing power. About two months before presenting himself for treatment he found that his voice became less clear; it varied very much; was better one day, worse the next, but never as good as before. It was a much greater effort for him to sing, and he tired out when he continued, and had actual pain in the throat when he persisted. At the same time he had a feeling as if a hard substance was present in his throat which necessitated frequent swallowing.

The patient had a considerable hypertrophy of the anterior portion of both middle turbinated bodies. They were snared off and relieved his catarrh. The follicular glands covered the base of the tongue rather uniformly, and it required treatment extending over two months to reduce them to their normal condition, and thereby to restore his voice to its former quality.

Case IV.—The last case I have selected from my notebook appears to me most interesting, and instructive at the same time. Miss J——, aged twenty-eight, was brought to my office by her mother, in a state of great anxiety, because the young lady was believed to be a victim of pulmonary phthisis. The patient had not lost much flesh, but she looked pale, anæmic, and was very weak, not having had one good night's rest for several weeks on account of her harassing cough. She had been under treatment before, and her chest had been pronounced "weak." Six years previously she had been treated for some aural disease, and later for a throat trouble, the exact nature of which I could not ascertain. On being questioned she said that for quite a long time she felt as though she must frequently swallow in order to overcome a raw, scratching feeling in her throat.

Most careful and repeated examination of her chest gave no evidence of pulmonary disease. Very slight granulations were present in her pharynx, but their destruction did not in the least relieve her cough. The follicular glands were, in her case, hypertrophied to such an extent as I have never seen since. There was a thick denseness of hypertrophic tissue extending over the whole base of the tongue, and covering the free border of the epiglottis completely. This mass was divided by longitudinal furrows, the deepest of which, centrally located, divided the whole tissue in two symmetrical halves. I began the treatment by snaring off each half with my platinum-iridium cautery-snare, and reduced the remaining tissue by repeated insertions of the cautery-knife. Improvement began immediately after the two parts I beg to show you here had been snared off, and, although the treatment extended over six weeks, no other means were employed, and a perfect cure was effected.

From the foregoing you will see, gentlemen, that the disease in question presents a great variety of symptoms. I purposely refrained from enumerating in detail all the different complaints patients have to make. I only endeavored to give the chief features we observe, without becoming tiresome. One point more, I think, is well worth dwelling upon. Although there are quite a number of people with enlarged glands who have no abnormal sensation, and therefore are not objects for treatment, we certainly have to look upon the hypertrophy of the tonsil of the tongue as another source of ailment of the upper air-tract which merits our undivided attention. It is not necessary to state, in an assembly like the one before me, that recent experience has taught us not to rest contented until we have found an anatomical basis for any neurotic symptoms the patient may suffer from. It is our endeavor to localize disease, and as long as we do not find the true cause our line of treatment is more or less without proper foundation. The symptoms enumerated above are not pathognostic of our disease, and without local examination a positive diagnosis cannot be made. If, therefore, in a given case, after a thorough examination of the usual localities, we find no definite cause for a certain train of symptoms, our attention should be directed to the base of the tongue before we assume a simple neurosis. The inspection of this organ requires no special manipulation, but it is easily seen in its full size when examining the larynx. As a rule, we are so accustomed to look at once into the larynx, and for the possible changes of its structure, that it will only need this suggestion to make the examination complete. When we are in doubt as to the locality giving rise to the abnormal sensations, we can avail ourselves of the action of cocaine, which arrests the reflex irritability, and thereby facilitates the diagnosis.

The prognosis is favorable, as well in regard to the disease itself as to the concomitant symptoms. Still I have found it difficult to pass judgment beforehand as to the time necessary for a cure, and in the beginning was more than once disappointed by giving a hasty opinion. They are not always the large hypertrophies which require most time for treatment; sometimes the reduction of a smaller but broader hypertrophic mass taxes the endurance of the patient and the resources of the physician a great deal more.

The line of treatment to be pursued is well marked out, and consists in reduction or destruction of the redundant tissue. Simple pressure with a cotton-carrier, applications of chromic acid, or of Vienna paste, have been recommended. My experience is limited to four remedial agents: Lugol's solution of different strength, nitrate of silver fused to a probe, the galvano-cautery, and, finally, the snare.

Lugol's solution is applied with the common laryngeal applicator, bent at a more obtuse angle and then introduced between the base of the tongue and the epiglottis. Although praised very highly by others, it has not proven so effective in my hands, and I now use it only in light cases or when patients object to the cautery. As one of its advantages I found in quite a number of cases that the patient feels at least temporary relief from his abnormal sensation immediately after the application. Lunar caustic is best adapted for cases in which the hypertrophic tissue is of a soft character and not so dense and compact as we usually find it. My best results I have obtained by means of the galvano-cautery, with which I make repeated scarifications into the follicular glands, and which acts here in a similar manner as when used for hypertrophy of the faucial tonsil. When there is contact between the epiglottis and tongue, care has to be taken not to injure the former, and the electrode has to be embedded firmly and deeply into the diseased tissue in order to avoid the epiglottis. The reaction is sometimes rather severe, lasting for several days, and ice-pellets and cocaine-spray may be employed to ease the patient. When the hypertrophic mass is lobular in shape, or so large as to enable its engagement in a snare, I consider it advisable

always to snare it off. With the proper use of cocaine the elastic cautery-snare of iridium and platinum answers the purpose as well as the cold snare, is not more painful, and, creating a larger slough, is more thorough in its action.

A CASE OF RIGHT LATERAL, OR HOMONYMOUS HEMIANOPSIA, WITH NEGATIVE HISTORY.

By ALFRED HINDE, M.D.,

SURGEON EYE AND EAR DEPARTMENT, CENTRAL DISPENSARY; INSTRUCTOR EYE AND EAR DISEASES, POST-GRADUATE MEDICAL SCHOOL; OPHTHALMOLOGIST TO NEUROLOGICAL CLINIC, RUSH MEDICAL COLLEGE, CHICAGO, ILL.

H. A. H——, married, Norwegian, carpenter, aged fifty-seven, somewhat anæmic-looking; first noticed a "blurring" of vision of the right eye—and only toward the right half of the visual field—some time between the latter part of January and the beginning of March last. This imperfect vision has qualitatively increased until complete blindness to the right has resulted, and he seeks advice solely on account of the increased difficulty in following his occupation.

His past history—carefully analyzed through a fellow-countryman and senior medical student—is negative as to consumption and syphilis, and he declares he "was never sick a day in his life.

About two years ago, when on a drinking-bout, he was struck by an associate with a whiskey-bottle on the left side of the head, at a point about one inch above and behind the external canthus. A slight wound, with little hemorrhage, resulted, but no discomfort followed until six months later, when, on exposure to inclement weather, he had some "cramp-like" pain in the left eyeball and in the anterior superficial region of the left side of the head. This pain recurs on exposure during cold, damp weather, and is probably rheumatic in character.

Never at any time has he had any headache, vertigo, nausea, tinnitus, or fits. He states that, though able to follow directions, his memory is not as good as formerly.

Present condition.—The right half of the visual field, and limited vertically, is absent in both eyes; in other directions the fields are normal. The fixation-point is central and, as is usual, is in the normal field. There is no paralysis of the external ocular muscles. The acuity of vision of the right eye is $\frac{20}{LX}$, and no glass improves it. That of the left eye is $\frac{20}{XL}$, and + 1.00 D., cylindric axis 90°, raises the vision to $\frac{20}{XXX}$. He reads No. VI. Snellen at 16″, without glasses; and with + 4.00 D., he reads No. I. S. at 8″ to 11″.

The color-sense is apparently normal, as is usually the case.

Both pupils are myotic—the direct reflex is observable, and the consentaneous, though present, is just perceptible. Owing to the myosis, the reflexes are necessarily limited.

Homatropine was used to dilate the pupils to render possible an intraocular examination, and no disease of either fundus was apparent; some astigmatism was evident—most marked in the left eye.

There is no ataxia, and the patellar tendon-reflex is normal. He follows his occupation, but reads with difficulty, because of the blind area being immediately to the right of the fixation-point, so that he cannot anticipate the context as in healthy vision.

The condition present is therefore a right lateral, or homonymous hemianopsia, dependent upon disease of the left optic tract; thalamus, or adjacent portions of the internal capsule; or of the left occipital cortical visual centre.

Etiology of the symptom known as hemiopia, hemiopsia, or hemianopsia: Transient hemianopsia is frequently observed in hemicrania, and is functional in character and dependent upon angio-neurotic origin.

Sudden permanent hemianopsia is due to cerebral hemorrhage or embolus. Hemianopsia of gradual onset is due to disease of the optic commissure or tract, one of the anterior corpora quadrigemina, the posterior tubercle of the optic thalamus, posterior limb of the internal capsule, or lesion of the occipital lobe, or due to tumors, syphilitic or tubercular disease of the base of the brain, or exostosis of the base of the skull.

A nasal or median hemianopsia is due to disease of both optic nerves (Leber). A superior or inferior hemianopsia is very rare and, if permanent, depends upon compression—above or below—of the optic tracts at the base of the skull, or symmetrical primary disease of the nerves. Lateral or homonymous hemianopsia is the form most frequently observed, and affects the lateral halves of both visual fields—either the external half of one field together with the internal half of the other, or it involves the temporal halves of both fields.

Where the temporal half of the fields is affected the disease is located in the crossed fasciculi at the optic commissure. If the right or left halves of the visual fields are missing, the lesion is situated back of the commissure in the opposite tractus or its posterior relations.

The pathology of our case is implied in the latter condition, viz., disease of the left optic tract, left anterior corpus quadrigeminum, posterior tubercle of the left optic thalamus or adjacent posterior extremity of the capsula interna, or of the left cortical visual centre apparently located in the occipital portion of the cerebrum.

On account of its gradual and indefinite onset cerebral hemorrhage and embolus can be ruled out; because of its permanency, some organic lesion is present.

Syphilis or large solitary tubercle may affect the optic tract or adjacent tissues, but, owing to the history, we may fairly presume these diseases are not present. Exostosis basis cranii may be present; or tumors of the pituitary gland, membranes, or brain-tissue may be the cause; or, again, the history of trauma given may have resulted in sclerosis (rarely single), softening, or abscess involving the cerebral centres named.

The differential diagnosis, without intracranial and focal symptoms, as in our case, is wellnigh impossible. Where tumor is the cause, unless of small size and very limited extent, some or all of the following cerebral symptoms are usually present: Headache, vertigo, vomiting, convulsions, dementia, etc., associated with choked disk, and possibly paralysis of other cranial nerves, especially the third, fourth, and sixth, hemiplegia being also frequently present. All the foregoing are absent in our case, and unless the tumor is small and benign we doubt its presence. With disease of the corpora quadrigemina third-nerve paralysis, with immobile pupil and nystagmus, is frequently observed. Again, disease of these centres is infrequent, and when present is usually only a part of the cerebral affection.

Destruction of the posterior tubercle of the thalamus produces complete hemianopsia of the opposite side (Strümpell). If the posterior limb of the internal capsule were the seat of lesion, we should have present, through involvement of the pyramidal tract, a more or less complete hemiplegia of the opposite side of the body. Moreover, the sensory path also lies here, and governs not only cutaneous sensation but also the organs of special

sense; therefore its destruction would result in hemianæsthesia of the opposite side of the body, together with impairment of smell, taste, and hearing, besides hemianopsia—in short, complete cerebral hemianæsthesia (Strümpell).

There is no hemianæsthesia present in our patient.

Traumatic abscess of the brain is usually due to extension of the suppurative inflammation from an open scalp-wound, easily understood where fracture is present, yet the latter is not essential; neither is an open wound a necessary concomitant, as experience has shown. Again, suppurative meningitis may be associated with abscess as a primary condition, or as a sequel to the latter by extension to the cortex. Moreover, we can have a metastatic meningeal inflammation, the mode of conduction from a distant part probably being through the blood and lymph-channels. The metastatic inflammation usually affects the convexity, the underlying brain being almost always involved, and important pressure-symptoms result.

Further, the onset of these prevalent meningeal inflammations may be insidious, but almost always the temperature is decidedly elevated though paroxysmal, and the case usually runs its course in one or two weeks, terminating fatally.

In these suppurating cerebral diseases, therefore, the pyrexia, with vertigo, headache, vomiting, etc., and preceded by ear, lung, or heart disease, or traumatism, we might look for an explanation of our case; yet, with the exception of slight trauma, these conditions are absent rom the history.

There is, however, one form of cerebral abscess—the so-called idiopathic—whose etiology is undefined and the invasion of which is uncertain. These latter, however, usually occur during periods of epidemic cerebro-spinal disease.

Brain-softening might best explain our pathology, and due to thrombosis dependent upon primary arterio-sclerosis or syphilitic endarteritis, yet the latter is denied by the history. The tissues, having lost their arterial blood-supply, degenerate into a softened mass, and, as a result, their physiology disappears. According to Strümpell, hemianopsia in diseases of the occipital lobe is well established, and, considering the age of our patient, together with the impaired cerebration complained of, and in the absence of symptoms, we are inclined to the belief that a localized brain-softening dependent upon a chronic primary arterio-sclerosis will best explain the phenomena of our own case.

The prognosis, save in syphilitic disease, is invariably unfavorable.

16 Laflin Street.

Dietary of Bright's Disease.—Dr. Fothergill gives the following. Breakfast: Oatmeal- or hominy-porridge, hominy-fritters, followed by a little fish with plenty of butter to it, or a slice of fat bacon or pork. Fat, fish, and farinaceous matters. Hominy and fat pork for the less affluent. Lunch or supper: Mashed potatoes well buttered. Other vegetables well buttered. A milk pudding made without an egg. Biscuits of various kinds, and butter, with a nip of rich cheese. Dinner: Soup containing plenty of vegetable matter, broken biscuit, or sago or vermicelli. Cream, in lieu of so much strong stock, should lurk in the soup-tureen, especially in white soup. This should be followed by fish in some form; a course of vegetables, as stewed celery, chopped carrots, a boiled onion, leeks, nicely prepared potatoes, as "browned potatoes" *à la* Marion Harland, asparagus, or "scalloped tomatoes," and corn or "boiled corn." Then should follow apple-bread pudding, Maud's pudding, bread-and-raisin pudding, and, if the digestion can be trusted, roly-poly pudding, sweet pudding, and fruit pies. Stewed fruit with creeled rice, rice milk or other milk pudding is good, or, better still, cream. Then comes the biscuit or crackers and butter. Dessert, with its many fruits, should never be omitted.

Clinical Department.

A VESICAL CALCULUS WITH AN UNUSUAL NUCLEUS.

By LEWIS W. ROSE, M.D.,

Assistant Surgeon, New York State Soldiers' and Sailors' Home, Bath, N. Y.

John B——, aged fifty-eight, was admitted to hospital suffering from urethral stricture and chronic cystitis. The stricture was cured by the introduction of sounds, and the urethra dilated so that a No. 19 English is readily passed. A stone having been detected, on November 9th a drachm of four per cent. solution of cocaine was injected deep into the urethra, and a Bigelow lithotrite passed into the bladder, by Dr. McNett. He seized a mass about one inch in diameter, and crushed. Much difficulty was experienced in withdrawing the instrument. After half an hour of careful and patient manipulation a leather shoestring, ten inches in length, was extracted, with but little discomfort to the patient. The string was massed between the blades of the lithotrite, and incrusted with phosphatic deposit. The patient denies any knowledge of how the string came into the bladder. He always enjoyed having sounds passed, and several times experienced sexual excitement during their introduction. At present he is progressing favorably.

A SIGN OF LIVE BIRTH IN CERTAIN CASES OF SUSPECTED CHILD-MURDER.

By F. W. HIGGINS, M.D.,

Cortland, N. Y.

It is well known that one of the most difficult questions which the medical jurist is called upon to decide is that of live birth where foul play is suspected. The hydrostatic test is about the only one which is at all conclusive. By this test, properly performed, one may quite positively affirm whether respiration has or has not taken place. But while killing the child in utero is criminal, and killing it after birth is murder, by a strange freak there is no punishment if the child be killed before it has been completely born, even after respiration has been fully performed. Nor does there seem to be any test given, by any authority, by which one may determine whether the birth were complete when death was inflicted. If I am not mistaken there are occasionally cases like the following, in which there is an additional important sign that may be detected: On May 21, 1887, I assisted Coroner George D. Bradford in an examination of an infant which collateral evidence showed was strangled at birth. The choking caused death, not so much by suffocation as by compression of the jugulars and hemorrhage at the base of the brain, and also by the condition found in the heart. The cord was cut off close to the body. Both cavities of the heart were found filled with dark, *frothy* blood. The conclusion arrived at was that compression had lessened the pulmonary circulation just as it was being established. The heart, still beating and unsupplied with blood, had *sucked* in air through the divided umbilical vein. Evidently this could have happened only after the body had come into the world and the cord, the last bond to the mother, had been severed.

A CASE OF ACONITE-POISONING—RECOVERY.

Dr S. Barnett, of New York, sends us the following:

"On November 13, 1887, at 5 P.M., I was called in haste to see E. L——, female, aged fifteen. Half an hour prior to my arrival the patient had by accident taken about half an ounce of tincture of aconite root. She was then lying on her back, conscious, with pale hands; the feet and legs were cold, the eyes were open, and the

pupils widely dilated; the radial pulse was imperceptible, and respiration was slowed. The girl was anxious and restless; she had some pricking in the lips and throat, and there was also emesis, which became quite copious later—not necessitating the administration of apomorphine, the action of which, moreover, I feared on account of the weak heart. The patient had for three years been suffering from interstitial nephritis.

"*Treatment.*—Hypodermatic injections of brandy, brandy internally, artificial heat to legs and feet, internal administration of about a quart of cold black coffee, head lowered, and feet raised. Under this treatment, in a quarter of an hour the patient began to rally; the pulse became perceptible, but was still thready, small, compressible, and intermittent.

"Paræsthesiæ were now developed. There were pricking in, and contraction of, the fingers and arm, of the toes and leg, of the left side. These caused the girl to cry out bitterly. Fingers were strongly flexed upon the palm, toes flexed, and leg was strongly bent on thigh. Vigorous massage, with the aid of brandy, over these parts, in the direction of sensory nerve-filaments, and of return circulation, quickly dissipated them. They persisted somewhat longer in the fingers than elsewhere. Later the patient had some pricking or "jumping" in her left side, which quickly disappeared.

"At 5.45 P.M. the condition of the pulse was anything but reassuring; it was extremely weak and intermittent. I resorted to several more injections of brandy and ether, and to the internal administration of brandy, and artificial heat to the feet and legs was kept up. Pulse would remain fairly good for from fifteen to twenty minutes, and then would perceptibly weaken. Still the patient was now materially improving. At six o'clock the girl was slightly delirious, having hallucinations of various kinds—she saw a man with big eyes, etc., and talked of persons deceased; would cry bitterly, and then laugh and pertly toss her head; would at other times gnash her teeth and struggle furiously, requiring two persons to keep her still, and at times it was necessary to prevent her from mutilating her features. She had several attacks which strongly simulated hysteria. She had no convulsion, nor was she ever unconscious. Stimulation still necessary. Fifteen minutes later, after many remedies and devices had been resorted to, the heart began to react strongly and steadily; the face became flushed, the extremities became warm, and the pupils began to contract. The patient was still somewhat delirious and very thirsty.

"At 7 P.M. the respirations were normal; surface-temperature normal; the surface was moist with perspiration, the pupils were contracting, the pulse was 88, and the patient was resting quietly."

FRAGILITY OF THE UMBILICAL CORD.

Dr. Julian La Pierre, of Norwich, Conn., reports the following case: "A few weeks since, in the absence of the family physician, I was called to attend a case of confinement. The presentation was an O. P., and of course the labor was of necessity slow and tedious. Before the termination of the case the physician returned, and very kindly came to my relief. As the pelvis was roomy, the child but medium-sized, and the mother strong, it was not deemed necessary to give any instrumental assistance. Soon after the doctor's arrival the head escaped from the vulva, and as it did so it became apparent that the cord was wound two or three times about the child's neck. Dr. —— at once proceeded to reduce the dislocation, and as he lifted one of the folds over the occiput the cord parted; he then quickly delivered the body, when it was discovered that the cord had separated by a diagonal fracture about one inch in length, and located between two and three inches from the umbilical extremity. The accident in no way proved detrimental to child or mother. I am confident that no undue force was used in removing the coil, and the cord and placenta were to all appearances normal, yet I regret that it did not occur to either the doctor or myself to examine more particularly and test experimentally the strength of the remaining fragment of cord. I have often noted in my own mind the remarkable uniformity exhibited in the brute creation by the parting of the cord near the umbilical extremity. The latter fact, coupled with the above experience, leads me to believe 'that the umbilical cord is frangible,' and furthermore, to entertain the query whether or not there is stay of development, fatty degeneration, or physiological absorption of the fœtal end of the cord during the last weeks of life *in utero*. We can hardly suppose our first mothers to have been provided with shears."

RUPTURE OF THE UMBILICAL CORD.

Dr. G. W. Squires, of East Avon, N. Y., writes: "I was hastily summoned to visit a woman, and upon arriving at the bedside was told by the husband that the child had been born the night before, but that the placenta had not come away. He stated that when making slight traction on the cord it broke, but that there had been scarcely any hemorrhage. The woman stated that she had had quite severe after-pains, which soon quieted down and she slept well all night. The uterus had expelled the placenta into the vagina, where it had remained until morning. It was easily and quickly dislodged. The cord had separated near the placenta. It was very white and of a fragile consistency, requiring but slight force to break it."

EPISTAXIS AND THE LIVER.

Dr. Harris Fisher, of Eastman, Ga., referring to a recent editorial notice concerning the causal relationship between nosebleed and hepatic troubles, reports a case from his practice. The patient was in the fourth week of typhoid fever, and was suffering from repeated attacks of epistaxis. Ergotine, gallic acid, hot water, cold water, ice, tannic acid, subsulphate of iron, veratrum, and morphine, and, finally, plugging of the posterior nares, had all been tried, with but slight and temporary benefit. The writer then determined to try the effects of a blister over the hepatic region, but on arriving at the bedside found that the hemorrhage had ceased. On inquiry he learned that Dr. Harrison had been called by the family to meet him, but as Dr. Fisher failed to arrive at the usual time, had ordered a mixture of oil of turpentine and lard to be applied to the abdomen, along with hot poultices. This prescription had been energetically carried out, with the result of producing a very decided degree of counter-irritation. In three hours the hemorrhage from the nose had ceased, and did not return.

FRACTURE OF THE COCCYX AND PASSAGE OF THE SEGMENT PER ANUM.

Dr. W. J. Jolly, of Waldo, Fla., reports the following case: "I was called to see Mrs. M——, November 1, 1887, primiparæ, aged twenty-one, who was in labor. Nothing unusual occurred until the head pressed against the coccyx, which did not yield. I applied the forceps, and delivered the woman without any trouble or laceration of perineum. Immediately after delivery she suffered intense pain in the region of the coccyx, for which I gave an opiate. On examination I found some displacement of the coccyx, which I corrected, supposing the bone to be fractured. The opiate soon relieved the pain, and the patient did not suffer any more until the ninth day, except that there was some tenderness in this region. She had some slight pain on that day; on the tenth she passed a bone per anum and sent it to me, stating that she thought she had passed a joint of her backbone. Upon examination I found it to be the lower segment of the coccyx. The woman has had no trouble since."

Progress of Medical Science.

Pott's Fracture.—In a paper on this subject Mr. Robert Jones states that, since the original description given by Pott, a hundred years ago, no great advance has been made either in the anatomy or treatment of the fracture associated with his name. The clinical signs of this lesion are, briefly, a depression over the side of injury, eversion of the foot, a prominent inner malleolus, and a swelling round the ankle-joint. The fracture takes place usually about two inches above the malleolus, the deltoid ligament being often ruptured, and the astragalus separated from the tibia. Dislocation of the foot outward, it is held, is not an essential and absolutely diagnostic symptom, as a slight outward displacement may occur on separation of the tibia from the fibula, without fracture of this latter bone, and outward displacement of the astragalus. Reference is made to two cases in which the fibula was certainly intact, although there was marked simulation of Pott's fracture. The precise spot of fracture, which varies in different cases to the extent of three or four inches, is often obscured by rigidity, due to swelling. The patient, guided by pain, is often able to place his finger on the exact point. On pressure upon the upper third of the fibula the patient is generally able to refer pain to the seat of fracture. As a rule, the surgeon can only guess at the direction of the fracture. Prominence of the inner malleolus, though always present, is not essentially diagnostic. It occurs in certain fractures of the lower end of the tibia, and in sprains of the ankle where laceration of the deltoid ligament has taken place, a tense swelling is often found sufficiently deceptive to lead to a possible error in diagnosis. It is very often difficult to make out crepitus in cases of this fracture. Eversion of the foot usually fails to cause this symptom. It is more likely to be produced by inversion, but the movement best calculated to elicit it consists in combined flexion and inversion. In twenty-nine out of seventy cases the lesion was complicated by fracture of the inner malleolus. The deformity in cases of Pott's fracture occurs and is intensified, Mr. Jones holds, through the continuation of the force which was employed upon the fracture. A foot is fractured by inversion, and then the deformity is generally inversion. Patients do not usually realize the extent of the injury, and continue to walk until a trivial becomes a marked deformity. Fracture due to direct force is less prone to luxation. In the treatment of Pott's fracture the reduction of deformity is accomplished the more readily in proportion to the absence of delay. The earliest chance should be seized of replacing the astragaloid luxation. The attempt at reduction should be long continued. If the reduction be completely effected there is no subsequent tendency to recurrence of the deformity, and, therefore, no necessity to employ splints devised to counteract special displacement. Lest, however, a little deformity remain, it is well to apply a couple of side-splints and a posterior splint, the side-splints being furnished with pads suitably arranged to minimize deformity. When the splints (which in Mr. Jones' practice are made of malleable sheet-iron) have been adjusted, the knee should be flexed and the leg be made to rest on its outer surface; the foot be maintained at a right angle to the leg. The injured limb should be kept in splints for fully five weeks. In conclusion, Mr. Jones offers a few suggestions regarding the treatment of cases in which, long after active treatment of Pott's fracture, the patients complain of pain, deformity, or inability to walk.—*The London Medical Record.*

Perineal Hernia.—The following conclusions are given by Dr. Ebner on the origin and nature of perineal hernia. Perineal hernia is of congenital origin. It cannot be produced by injury. The space between the bladder and rectum, in the female between the rectum and uterus, is deeper and more marked in embryonic than in later life. Persistence of this space establishes a tendency to the formation of perineal hernia. The depth of this space varies in different embryos of the same age. The contents of the hernia at first descend in the middle line, but as they become more superficial they deviate to the right or left side of the perineum. Perineal hernia usually makes its way between two clefts existing between the levator ani and ischio-coccygeus muscles, or between the latter muscle and the coccygeus of Henle. These clefts may be demonstrated on the human cadaver. All ruptures that appear at the lower aperture of the pelvis are to be regarded as varieties of the same kind of hernia. A classification of perineal ruptures, according to their position with regard to the transverse muscle, is impracticable. The perineal hernia of the dog consists in a protrusion without any sac of the rectum through a wide cleft in the levator ani. A similar protrusion may occur in man, and be acquired as a result of habitual constipation.—*Deutsche Zeitschrift für Chirurgie.*

Disease of the Hair-bulbs and Blepharitis.—Dr. Roeder, in 1861, while studying skin diseases under Hebra, recognized the identity of blepharitis and sycosis, and has adopted the same treatment—epilation—for both affections with good results (*The London Medical Record*). From the examination of a large number of cases he has come to the conclusion that the cause of the blepharitis is the inoculation of the hair-follicle with purulent secretion from the conjunctival or lachrymal sac. In the early stage of stenosis of the lachrymal duct, before there is any blennorrhœa of the sac, one often sees tears accumulate in the lower cul-de-sac. As long as there is no pus, the cilia remain healthy; but, as soon as there is the slightest admixture of pus, blepharitis makes its appearance on the under and corresponding part of the upper lid. The writer considers this so constant that he would diagnose the presence of lachrymal obstruction and blennorrhœa of the sac. The writer explains the action of the pus thus: As long as the fluid in the cul-de-sac which bathes the openings of the hair-follicles consists simply of tears, the sebaceous secretion from the glands of the hair-follicles prevents it from entering the latter, but the admixture of alkaline pus allows a fatty emulsion to form, which readily enters the follicles. The hair then swells up by imbibition of moisture, thus closing the orifice of the follicle, and causing distention of the latter. If the pus escape through the surface it appears as little crusts between the lashes, often accompanied by little, warty prominences. In slight cases the follicle again embraces the hair, the glands resume their function and prevent the further entrance of tears, and the normal condition is restored. But it is a necessary condition that the purulent secretion from the conjunctival or lachrymal sac should first cease. Usually recovery does not take place so readily. The hair is at first retained in the follicle by the swelling it has undergone. The whole process may be repeated thirty times or more. Infection of the hair-follicle, throwing off of the old, and growth of the new hair. But in course of time cicatricial contraction of the whole follicle takes place, so that the young hairs, meeting with an obstacle to their exit, become curved. If the obliteration of the follicle reaches a still higher stage, the dead hair may be retained and acts as a foreign body. The writer believes that a cure can only take place when all the affected lashes have been shed or removed; but, if the new hairs are not also to become affected, it is absolutely essential that the conjunctival or lachrymal affection should be cured; as long as this is not the case, the new hairs must be removed as they appear. The writer uses a four per cent. solution of boracic acid as a lotion. The erysipelatous swelling of the lid, which is so frequent an accompaniment of this affection, also disappears under this treatment, which the writer has found usually efficacious in sycosis of other parts.

Salicylic Acid in Food and Drink.—The effect of this acid upon health has been thoroughly investigated in France, and its use in foods and drinks has been prohibited in that country since 1881. Professor Bartley, of the Long Island College Hospital, has recently examined this question with great care. In the use of salicylic acid in the treatment of rheumatism, clinical observation shows that it cannot be continued for a long period of time without impairing digestion, and in its elimination it passes out undecomposed through the kidneys. It has been recognized that under these circumstances it not only irritates but inflames these organs. In preserved food we have to do with smaller quantities of the acid, as a rule; though that this is not always the case is shown by Professor Bartley's figures. He says: "The quantity of salicylic acid usually employed in wines is from six to eight grains per gallon, and in beer from twelve to fifteen grains per gallon; or, in the case of beer, from one to one and a half grain to the glass. As many men habitually drink twenty-five glasses during the day, they take from twenty-five to thirty-seven grains of the acid per day. The medicinal dose is usually stated to be from ten to twenty grains." He also calls attention to the fact that nursing mothers are frequently recommended to drink ale, porter, or beer, with the idea that it stimulates the mammary gland, and mentions the additional fact that temporary renal disease is frequent during the first weeks of lactation. In conclusion, Professor Bartley says: "I should state that another serious objection to the use of salicylic acid is the fact that many samples found in the market contain more or less carbolic acid. It is now almost entirely manufactured from this very poisonous substance, and, unless great care is exercised, an appreciable amount of it is left in the finished product. Indeed, some writers think that some of the fatal accidents recorded from the use of salicylic acid have been due to the presence in it of carbolic acid. If the use of this acid is to be countenanced, impure articles will be used, and greater damage may be done than could come from the pure article. From a careful consideration of the whole subject, I am compelled to regard the use of salicylic acid in foods and drinks, and especially in lager beer, as at least open to serious objections. If it be harmless to healthy adults, the evidence of its deleterious action upon the aged and certain other classes of the community is too strong to be disregarded by sanitary authorities, and should prohibit its use for this purpose."—*Science.*

Antagonism among Bacteria.—Dr. Garré has been examining the mutual relations of micro-organisms, and has found that in cultivation there is a sharp antagonism among some, probably through their excretions. For instance, some aërobes, which spread only on the surface of gelatine, in a short time so alter the nutritive substratum that certain other micro-organisms cannot exist in it. Various observations made in the cultivation of cholera and typhoid bacilli, and experiments on the multiplication of pathogenic bacteria in water have shown that there is probably antagonism between the pathogenic species and ordinary harmless saprophytes. To elucidate this, Garré adduced the following facts: A non-liquefying cultivation was planted on the surface of meat-peptone gelatine. After complete development, it was removed with the usual sterilized platinum wire. Other micro-organisms were then planted on the remaining sterilized medium. A comparison of the retarded growth with another cultivation gave the degree of antagonism between the two species. With liquefying species the nourishing substratum was filtered through potter's earth, and gelatine added afterward. In this way the mutual relations of a number of pathogenic and non-pathogenic species were tested. One species proved to be pre-eminently antagonistic—viz., the *bacillus fluorescens putridus* (Flügge). It excretes specific substances, the oxidation-products of which tinge the gelatine with a greenish color, and hinder the development of the one set of species, while it has no effect whatever on the other set. If such cultivations were removed from the gelatine in the manner described on the third or fourth day, and the staphylococcus pyogenes aureus inoculated on this medium, no development took place, nor did the typhoid bacillus, the pneumonia bacillus, and others develop. The Asiatic cholera bacillus and the bacillus mycoides developed but slowly, but the bacillus anthracis had a luxuriant growth. It appears, therefore, that the bacillus fluorescens putridus is a pronounced enemy of the pneumonia and typhoid bacilli, and by its implantation the nutritive substratum is protected against them. The reverse, however, does not hold good. There are also so-called symbiotic bacteria that flourish side by side, and some even, which Garré terms metabiotic bacteria, whose existence depends on the presence of others. He asserts that these facts are not confined to experiments in test-tubes. He points to the strife between saprophytes and cholera bacilli in ichor and canal water. The cholera bacilli always succumb. Similar conditions may occur in the intestine, and may in some cases lead to the erroneous supposition of natural indisposition to cholera. The torpid development of periostitis of the jaw, when the staphylococcus must come into conflict with other species, is explained by Garré on the supposition of such antagonism. He presents the following points as regards immunity: Immunity from a certain disease may be caused not only by micro-organisms of like species (vaccination), but perhaps by entirely different microbes. Antagonism quickly produced in the living body may favorably affect infectious diseases already existing.—*Deutsche Medicinische Wochenschrift.*

Spontaneous Displacement of the Lachrymal Gland.—Dr. Lyon reports a curious case of spontaneous displacement of the lachrymal gland. A man, aged sixty-three, applied for advice, as he was suffering from ptosis and a tumor situated in the right upper eyelid, which by its weight caused the ptosis. The skin over the tumor, though slightly congested, was not œdematous, and was freely movable. The patient stated that four months previously he noticed a swelling about the size of a bean in the upper eyelid, giving no pain, but causing inconvenience from the ptosis it caused. It was also noticed that the right eye was more watery than the left, and that the swelling was larger in the morning, becoming rather smaller during the day. The tumor was perfectly painless, even on pressure; the neighboring lymphatic glands were not enlarged, and the patient seemed in perfect health. Under these circumstances the diagnosis was made of displaced and chronically enlarged lachrymal gland. An incision was made over the tumor in the long axis of the upper lid, and the gland, which was lying immediately under the skin, was turned out. The accessory portion of the gland was found in its usual position, and was left undisturbed. The ptosis soon improved, and the patient made a good recovery.—*The Edinburgh Medical Journal.*

Solutions for Washing Out the Bladder.—Ultzmann, of Vienna, uses the following with good results: For an irritable bladder lukewarm water with a little tincture of opium; or solution of cocaine, $\frac{1}{4}$ per cent.; or resorcin, $\frac{1}{2}$ per cent.; or carbolic acid, $\frac{1}{6}$ per cent. When urine decomposes in the bladder, solutions of potassium permanganate, $\frac{1}{10}$ per cent., or three drops of amyl nitrite to a pint of water. For phosphaturia, $\frac{1}{10}$ per cent. salicylic acid.—*Centralblatt fur Chirurgie.*

Pernicious Anæmia, so called, may serve as another cause of gall-stones, according to Georgi and Professor Ewald.

St. George's Hospital, London, has received a bequest of $500,000.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 17, 1887.

TYPHOID FEVER AS A CAUSE OF CARDIAC AND ARTERIAL DISEASE.

WHILE it is recognized that any of the essential fevers may cause an endocarditis or arteritis, typhoid fever has generally been thought to have but little influence in this direction, especially as compared with rheumatism, measles, and scarlet fever. Three years ago Dr. Barié (*Rev. de Médecine*, January and February, 1884) claimed that typhoid fever frequently caused inflammation of the arteries. In such cases gangrene results in one form of the inflammation, which is an obliterating arteritis, while in the other form, in which there is an acute parietal arteritis, recovery always occurs.

Further studies of the relations of typhoid fever to the vascular apparatus have been lately made by Landouzy and Siredey (*Revue de Médecine*, September and November, 1887), and these gentlemen claim to have established some very important facts with regard to the matter in question.

This fever, they say, may lead to acute cardiac changes, which produce the collapse or syncope sometimes seen in the later or convalescent stages of the disease. But, furthermore, typhoid fever often leads to the slow and insidious development of chronic endocardiac and arterial disease. The authors to whom we have referred assert that after acute rheumatic fever, typhoid fever, of all infectious maladies, is the one which oftenest leads to the development of angio-cardiac disease.

The poison of typhoid fever sets up a tendency to a progressive obliterating endarteritis. This, as years go by, affects the nutrition of the heart, arterial walls, and viscera, and there finally appear, some months, or oftener some years, after the fever, hypertrophy of the heart, aortic dilatation, tense arteries, visceral scleroses, etc., with various functional disorders, such as palpitations, angina, and abnormal *bruits*. The man who has typhoid at twenty will thus understand why he comes to have cardiac disease at twenty-five, or a nephritis at thirty, or a hepatitis at thirty-five. And the prevention of typhoid fever will, according to our authors, greatly lessen the number of sufferers from angio-cardiac disorders.

The views we have just described are unfolded by MM. Landouzy and Siredey at great length and detail. Fifteen observations are recorded, in some of which the development of the pathological process was carefully watched for a course of years. It will require much further work, however, to convince pathologists of the truth of the position taken. Typhoid fever is a disease of the younger periods of life, the angiopathies and scleroses belong to a much later stage, and the attempt to establish causal relations between the two is most difficult.

THE TEACHING OF MEDICAL ETHICS IN MEDICAL COLLEGES.

WE have had occasion at various periods to deplore the complete absence of ethical instruction in medical colleges. By ethical instruction we mean, not especially the rules of right conduct as regards the ordinary relations of life, the need of honesty, purity, generosity, and the other major virtues; but the young graduate needs to know more than he ordinarily does concerning technical ethics, the established courtesies, and, in general, the minor morals and manners of professional life. Few of these points can be learned in any written code; and, indeed, no fixed code could ever tell, with the force and impressiveness such as a teacher might give, the details to which we refer. Much of professional success, and all of professional good-will, depend upon the exhibition of proper tact, forbearance, good taste, and good sense toward patients and colleagues. And many young men early get in trouble with their seniors because they are not aware of the imperative necessity of exercising these qualities.

Some of the things in which mistakes are ignorantly made are in connection with consultations, and the etiquette connected with these; or regarding the treatment of patients previously under the care of other physicians. Some useful injunctions might be given as to the evil practice of talking against a brother practitioner's methods of treatment, the malicious exploiting of his failures, and in general the use of uncharitable inuendoes. It is sadly true that in many of the smaller towns the medical men live in unpleasant, even bitter, antagonism with each other, with the result of throwing discredit on the profession and impairing the usefulness and progress of our art. Doctors need to be inoculated with a great deal more of the gospel of charity toward each other, and a few lectures for promoting this would be very useful. But besides this, there are many other details, which seem somewhat trivial but which could be wisely discussed; such, for example, as the limits of legitimate advertising, the printing of cards, and the character which good taste should prescribe for the signs. The exigencies of modern pharmaceutical enterprise call also for some words of counsel regarding proprietary and patent medicines, and fancy "foods" of all kinds. Many physicians ignorantly use the former articles, at least when they might much better stick to the Pharmacopœia.

We have shown that there is a large field for didactic instruction outside the ordinary course of lectures, and we trust that our medical colleges will inaugurate a movement in the direction we have suggested.

A NEW METHOD OF EMPLOYING IODINE FOR ANTISEPTIC PURPOSES.

IT cannot escape the attention of the observant that antisepsis in surgery has come to stay. But what may be termed "antiseptic medicine" has not hitherto re

ceived a corresponding amount of attention from the medical world. That the ultimate aim of medicine is prevention will be conceded by most physicians, and there is, no doubt, a growing confidence in the value of antiseptics as prophylactics, and even as curative agents. Drs. Casson and Brownen (*The Medical Press*) emphasize the fact, familiar to many of us, that in the treatment of infectious diseases the remedies employed for the protection of attendants, or for the prevention of the spread of infection, may produce satisfactory changes in the condition of the patients themselves.

It has occurred to these observers that iodine, slowly evaporated, might prove a useful adjunct to other means of treatment in dealing with this class of affections. They cite the circumstance that, according to Koch, the only *effective* disinfectants, besides chlorine, bromine, and iodine, are corrosive sublimate, osmic acid, and potassic permanganate. They necessarily exclude the mercurial sublimate from consideration. "Valuable, perhaps the most valuable, as it is among antiseptics for local surgical application, its highly poisonous character forbids its employment as a general medicinal disinfectant." Osmic acid and bromine are too expensive for general use, and the offensive odor of the latter would also militate against its employment. Chlorine has the same objections from the disagreeable pungency of its vapor. The potassic permanganate is also comparatively valueless unless employed in considerable strength. Iodine, however, presents none of these disadvantages. It has long been recognized by all authorities as a true germicide disinfectant.

But they point out that its employment as a general disinfectant has been greatly lessened, owing to the difficulties experienced in its regular and gradual vaporization. Combined, however, with salicylic acid, they find that "it can be readily and permanently incorporated with fats, paraffins, or wax, and when candles made from these hydrocarbons thus treated are ignited, iodine and phenol are evolved in a gaseous vaporized form. The phenol is produced by the decomposition of the salicylic acid, and its amount varies according to the temperature or rate of the combustion. Its presence may be verified by passing the vapors of the combustion through dilute nitric acid, and thus producing trinitrophenol or picric acid. But where the combustion is rapid and complete the phenol is entirely destroyed, as all other *organic* materials, such as eucalyptus, which has been suggested for somewhat similar treatment, must necessarily be. It is not so, however, with regard to the iodine. Being *inorganic*, it is wholly volatilized and thrown out as vapor into the surrounding atmosphere, but it is in no sense destroyed. Its presence in the gaseous products of the combustion may be demonstrated by passing them through a solution of starch, or along a tube moistened with starch mucilage. In either case the iodide of starch is speedily produced, and may be recognized by the usual tests. A very faint odor of iodine may be detected when these candles have been burnt in quantity in a close atmosphere; but this is never unpleasant, or in the least degree irritable to breathe; indeed, in several cases of asthma, spasmodic cough, and 'hay catarrh,' the patients have experienced great relief from the iodine vapor thus liberated. As a deodorizer its action is most marked; the smell of tobacco smoke is quickly and entirely destroyed by the combustion of these candles in the smoking-room. The air of stuffy rooms and smelling closets may be rapidly purified by the same means. The odor of sulphuretted hydrogen and of ammoniacal air from a close stable have been very speedily and completely discharged by contact with the same vapor."

It is, of course, too soon to say positively that this method will prove of value when tested on a large scale, but it is suggestive enough to deserve a trial, and this will doubtless be given it by those who are in a position to observe numerous cases of infectious maladies.

News of the Week.

A Prize for Essay on Anthropology.—The President of the New York Academy of Anthropology announces the following prize for original essays on any subject within the domain of Anthropology: For the best essay—Fifty Dollars. The prize to be awarded by a commission, to be named by the President of the Society, which will be hereafter announced. Competition will be limited to active, honorary, and corresponding members of the Society at the time the award is made. It is intended to make this prize open to all students of Anthropology throughout the world, as all competitors may apply for membership in the Society, which now has active members in most of the American States, in Canada, and in many foreign countries. The papers must be sent to the President of the Academy, Edward C. Mann, M.D., 128 Park Place, Brooklyn, N. Y., on or before April 1, 1888. The name of the author of any paper will not be communicated to the Committee awarding the prize. All persons desiring to compete for this prize will please forward their names and address to the President of the New York Academy of Anthropology. In case the essay is written in a foreign tongue, it should be accompanied by a translation into the English language. Every essay must have a motto, and in a sealed envelope must be written the name and P. O. address of the author, with the motto of the essay also. It is hoped that all our members, whether active, honorary, or corresponding, will take an interest in this effort to stimulate scientific inquiry and research in questions relating to Anthropology. Scientific societies are invited to lay this announcement before their members, and the co-operation of the legal, medical, and public press is respectfully solicited in bringing the subject to public attention.

Thirty-five New Dispensaries for New York.—An effort is on foot to organize a new system of dispensaries throughout the city on the provident basis. We have already referred to the opening of one establishment. But it is proposed to start thirty-four others. We trust the managers of this enterprise will investigate the subject of the medical charities of this city carefully before undertaking their proposed scheme. The so-called provident-dispensary system has not gained unqualified approval in England; and in this city it has been used as a shield for quackery.

Toronto is to have a new hospital costing $150,000.

Typhoid Fever recently developed at the Norristown Insane Asylum. Like certain other medicinal measures, it killed some, but it also cured several patients who had suffered for some time from insanity. Erysipelas has been known to do the same thing.

Our Sympathies are instantly touched by the title of *The Medical Waif*, a new monthly journal, published at Lafayette, Ind., and devoted to Diseases of Children, Women, the Rectum, and Anus. Exactly why women and children should be thus nosologically associated with the rectum and anus we hardly know, since these parts of the anatomy belong equally to man. But *The Waif* appears to be a journal of good typography and positive convictions, and it will doubtless explain itself in time.

A New Crematory has just been completed at Detroit, Mich.

St. Francis' Hospital, New York.—Dr. George M. Edebohls has been appointed gynecologist in place of Dr. G. S. Winston, resigned.

Dr. B. A. Watson has resigned his position as Visiting Surgeon to St. Francis' Hospital, Jersey City. We are requested to state that no further changes have been made by the board since the appointment of Dr. McGill.

The Effects of High Atmospheric Pressure.—Dr. Samuel Sexton writes: "Will you kindly afford space in the columns of The Medical Record for the correction of a mistake at the beginning of my article on 'The Effect of High Atmospheric Pressure on the Ear,' in your last issue? It says: 'Travellers rapidly transported to high altitudes often experience unpleasant symptoms from this cause' (high pressure). The writer had intended to cite this as an example of one of the effects of the opposite condition—rarefaction—where distention within the drum of the ear may take place in consequence of rarefaction without, causing distress until the equilibrium is again established."

The Number of Medical Women in New York City is said to be about one hundred and seventy.

The Next Middleton Goldsmith Lectures of the New York Pathological Society will be delivered by Dr. Da Costa, of Philadelphia.

Gonorrhœa and Sterility.—Dr. William Goodell says: "Personally I cannot recall a case in which a woman bore a child after suffering with gonorrhœa. Strumpets rarely become pregnant, for most of them have had this affection."

Carbolic Acid in Epithelioma.—Professor Bartholow used for a long time a five per cent. solution of carbolic acid in a case of *epithelioma*, injected hypodermatically two or three times a week; not curing, but preventing further growth after two surgical operations had failed to remove the trouble.

The Sänger Cæsarean Operation has now (*Medical News*) been performed fifty times, chiefly by continental surgeons, with the result of saving forty women and forty-eight children. With this record the operation is to be regarded as a most brilliant one, and the *News* asserts that when promptly conducted it is safer than craniotomy, where the true conjugate of the pelvis is reduced to two and a half inches.

The Homœopathic College of this City has purchased a plot of ground on the Eastern Boulevard, near Sixty-fourth Street, where it will erect a college and hospital.

The Army Medical Museum has been moved from the old Ford's Theatre to a fire-proof building near the Smithsonian Institution.

Mr. Clay and Chian Turpentine.—Mr. Clay recorded last year the case of a gentleman whom two of the most experienced surgeons in London had pronounced to be the subject of advanced epithelioma of the tongue. Under the Chian-turpentine treatment he was cured. And last month *The Lancet* published a further short paper, containing no less than four cases in which the diagnosis of cancer was made by other surgeons, in one case confirmed by microscopic examination of a growth removed. All of these cases were first improved, and then cured, by Mr. Clay's treatment.

The Cancer Bacillus alleged to have been discovered by Dr. Scheuerlen, of Berlin, does not seem, on further investigation, to be a genuine specific bacillus. Dr. Scheuerlen's conclusions are as follows: (1) There exists always in cancerous tumors a bacillus which can be isolated; (2) the spores of this bacillus are met with in all microscopical preparations of cancerous tissues; (3) inoculations upon animals with pure cultures of this bacillus always give rise to the formation of cancerous tumors; (4) there is, consequently, a causal relation between this bacillus and cancer. The bacillus in question is from 1.5 to 2.5μ long and 0.5μ wide. The spores are all of the same size, 1.5μ by 0.8μ, of ovoid shape, slightly green, and shining. The bacilli move like the weight of a pendulum round a centre.

It is said (*Peoria Medical Monthly*) that the late Professor Moses Gunn left a fortune of $50,000 as the result of a long, laborious, and successful professional career.

The New York Eye and Ear Infirmary is trying to get a new building, and already, we learn, $60,000 have been subscribed.

Lanolin is said to remove wrinkles when rubbed systematically upon the skin.

Seasonal Changes in Body-weight.—In the annual report of the health of the Japanese Navy is the record of weight measurements of the sailors, taken monthly for three successive years. The average weight is about one hundred and twenty-two pounds, and there is a fall in weight during the autumn and an increase in the spring, when the maximum is reached.

Bequests to Medical Charities.—By the will of Mrs. V. B. Humphrey, of Norfolk, Conn., the Bellevue Hospital Training-School gets $6,000; Brooklyn City Hospital, $6,000; Connecticut Training School for Nurses, $6,000; and Long Island College Hospital, $10,000.

The Virginia Medical Registration Law.—It is proposed to amend this law so that it will require candidates to appear for examination before the board in session, instead of before three individual examiners as now allowed.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, November 15, 1887.

C. L. Dana, M.D., Chairman.

Dr. J. Blake White reported a case of

ICTERUS NEONATORUM,

which he saw with Dr. Henry Moffatt, of Yonkers. Up to the sixth day of life the baby nursed, and nothing unusual was noticed except that the icterus increased. On the seventh day it had a slight convulsion. The icterus increased and convulsions continued until the twelfth day, when the child died.

The autopsy revealed large liver, normal appearance of the hepatic ducts, constriction of the cystic duct, and the common duct was impervious throughout its entire length. The left lung was collapsed entirely; the right was fully expanded.

Dr. White then gave a *résumé* of the reported cases of malformations of the liver, ducts, and gall-bladder.

Dr. H. N. Heineman then read a paper with the title,

WHAT CONSTITUTES A CARDIAC MURMUR?

the object of which was to provoke discussion on the question, What constitutes a cardiac murmur, and what does it signify? that would lead to a narrowing of the data upon which organic disease of the heart should be diagnosticated. A murmur was defined as an adventitious or abnormal sound developed in the heart or blood-vessels. The changes in the heart's normal sounds were those of exaggerated intensity, diminished intensity, and duplication. These changes accompanied not only the normal sounds, but pathological conditions of the heart, and almost imperceptibly one might be assumed for the other.

The author of the paper enumerated the conditions in which reduplication of the first and of the second sounds occurred. With regard to hæmic murmurs he believed, contrary to Hayden, that they were heard at the apex as well as at the base. Then followed a description of the dynamic and the pseudo-murmurs, exo- and endocardial.

Dr. A. L. Loomis said that Dr. Heineman had given a very careful review of the history of the cardiac murmurs, and he had waited patiently for some definite conclusions to which the author of the paper would arrive. It seemed to him that the more one studied cardiac murmurs, the less reliance would be placed upon them as positive indications of any cardiac disease which prejudiced life seriously. He had felt, for a considerable time, that the murmurs spoken of as friction endocardial were not due to friction, but that all cardiac murmurs were vibrating sounds produced within the blood-current. If that explanation was correct, there were many such sounds heard in and about the heart which had but little, if any, pathological significance. He had long been convinced that

THE PRESENCE OF A CARDIAC MURMUR,

in itself, could never be accepted as a positive sign of cardiac disease; for, oftentimes, the most serious lesions at the valvular orifices were not accompanied by cardiac murmurs, and frequently murmurs ceased while the lesions which produced them at one time still existed. The simple fact of the presence of a cardiac murmur told but little, unless the other cardiac conditions were take into account, and the effect which they produced upon the general circulation, or, as Dr. Heineman had said, the clinical history of the case was considered.

Most of the murmurs produced outside of the heart, he had concluded, were cardiac respiratory murmurs. All the true hæmic murmurs were heard

AS OFTEN AT THE APEX AS AT THE BASE,

and the old statement that the anæmic murmur was produced only at the aortic orifice he regarded as faulty.

The great question to be determined was the condition of the cardiac wall, which regulated the amount of cardiac force.

In anæmia the cardiac force was in many cases diminished to such an extent that practically the ventricular walls allowed regurgitation at the mitral orifice. Such murmurs were no more nor less than anæmic, even though they had the characteristics which were signs of mitral regurgitation. Therefore in deciding whether a murmur was due to changes in the blood, it must be decided concerning the power of the heart. With regard to

ORGANIC LESIONS OF THE HEART,

when there was stenois and also changes which permitted regurgitation, the significance of those murmurs was not determined by their point of maximum intensity, or area of diffusion, or by any quality they possessed, but entirely by the amount of cardiac dilatation which might be present, the cardiac hypertrophy that might accompany them, or the absence of hypertrophy and the excess of dilatation. When dilatation had reached the point of producing marked disturbance of the general circulation, the mitral and aortic murmurs might disappear.

Dr. A. H. Smith thought that any one who had watched heart affections for many years, and had had opportunity to observe the results of autopsies would reach the conclusions:

First, that very many decided murmurs had very little anatomical basis; and

Second, that the great variety of changes which might take place would necessarily produce a great variety of sounds; and that it would be almost as impossible to determine what would be the sound corresponding to each lesion as it would be to find two faces exactly alike.

He thought the tendency had been to exaggerate the importance of cardiac murmurs, *per se*. He related an illustrative case, in which there was a loud murmur present when the patient was a young person, yet there was apparent recovery, and life had been already prolonged many years, with the person still in the enjoyment of a fair degree of health. The lesson taught was that

LESS SIGNIFICANCE

was attached to cardiac murmurs than was the custom formerly. The general condition of the patient and the evidence of imperfect circulation were the important aids in forming a prognosis.

An intercurrent disease, such as pneumonia, might render the cardiac disease more prominent, and decide a case unfavorably.

He believed that the presystolic murmur was produced in the interval between the *beginning* of the systole and the *production* of the first sound, and therefore that those murmurs which

END ABRUPTLY WITH THE FIRST SOUND

were systolic and not diastolic.

He had heard the hæmic murmurs more over the body of the ventricle than over either orifice.

Dr. S. S. Burt said that while he so completely accepted what Dr. Loomis had said as to render it nearly unnecessary for him to speak, yet he believed that some cardiac murmurs were so often associated with definite lesions that they were of great assistance in making a diagnosis. Certainly murmurs existed without cardiac disease, and grave cardiac disease might be present and no murmur produced; but the diagnosis should be made upon the history and symptoms, together with the condition of the cardiac muscles. If the murmur was due to vibra-

tion in the blood-current, and the loudness of the murmur depended upon the strength of the cardiac contraction, a loud murmur might indicate a strong heart. He had been accustomed to regard

A DIASTOLIC WHIFF

heard at the middle of the sternum as indicative of serious aortic disease.

There were many cases of anæmia without cardiac murmur. When a murmur was present in such cases it was usually heard at the base, although now and then it was heard at the apex.

Dr. Francis Delafield said that Dr. Heineman's paper had brought out in bold relief the different opinions with regard to cardiac murmurs, and certainly they were things that had suffered somewhat at the hands of their friends. There had been too many descriptions and too many explanations of cardiac murmurs; explanations pushed into attention without any very weighty considerations.

Surely it would be very satisfactory if all could have the same

IDEA AS TO WHAT A CARDIAC MURMUR IS.

It seemed to him that some common understanding should be reached, and the way to arrive at that understanding was not by increasing, but by limiting the number of cardiac murmurs, and being more and more strict as to what shall be called heart-murmurs, independent of lesions. There were three points which were altogether different.

1. It must be determined whether the sound heard could be properly called a murmur independent of heart disease.

2. It must be determined whether or not the person had anatomical disease of the heart.

3. It must be determined what was likely to occur, provided he had anatomical disease of the heart; for it was very well known that anatomical disease of the heart was perfectly well borne, although it was not a good thing to have. While it was too much to hope for that we were likely to give the same interpretation to what was heard, it did seem to him that we might agree, as to what we did hear, as to what should be called a heart-murmur.

Although he could not lay down any data, his own feeling was that the way to solve the problem was to be as strict as possible, and not call any sound a murmur unless it was

A NEW SOUND ADDED TO THE NORMAL SOUNDS.

Dr. Kinnicutt's experience coincided with that of Dr. Loomis with regard to the site of the murmurs of anæmia. He believed they were heard almost as frequently at the apex as over the pulmonary area, the latter being by far the most frequent situation of *basic* hæmic murmurs.

He was convinced that any differential diagnosis between a functional and an organic mitral regurgitant murmur, based upon the dictum laid down in most text-books, that the latter alone was conducted to the axilla and the angle of the scapula, must often be incorrect. The conduction of a mitral regurgitant murmur depended largely upon its intensity. A loud murmur, either functional or organic, would probably be so transmitted; a weak murmur, on the contrary, rarely would be heard in these situations. A loud mitral systolic murmur frequently coexisted with little or no disease of the mitral valve, a weak murmur with the gravest lesion. Dr. Kinnicutt thought that the theoretical considerations in support of the pathology of the præ-systolic mitral murmur, as recently restated by Dr. Dickinson, very convincing.

He asked Dr. Delafield if he had any way of distinguishing between a mitral functional and a mitral organic murmur.

Dr. Delafield knew of no way of distinguishing by the murmur, but was guided altogether by other considerations.

Dr. Jacobi remarked that the credit of the observations of Rosenbach, referred to by Dr. Heineman, should be given to Potin, who, three years ago, fully described these murmurs due to interruption of inspiration. He thought that diagnosis of chronic heart-disease should not be made unless there were changes in the size of the organ, for there were organic sounds which disappeared, and it was well known that children with adventitious cardiac sounds might get rid of their systolic murmur. Such children might reach adult life and do very well. An illustrative case was cited; that of a man, now thirty years of age, who was sometimes inconvenienced by his heart, but was in very good general condition, at this remote period, from his rheumatic endocarditis of childhood.

Dr. Loomis said that one remark made by Dr. Jacobi had brought to mind the observation that children might have valvular lesions accompanied by a murmur, and the murmur grow less and less distinct as adult life was reached, and those subjects would suffer only slightly, if at all, from cardiac symptoms, until the degenerative period of life was reached. But as soon as that period was arrived at, the more serious symptoms developed and their life-record was limited to about that period. He had noticed that fact in quite a number of instances, and it was

A POINT WHICH HE HAD NOT HEARD MENTIONED.

Dr. W. M. Carpenter remarked that a physician who had had a large experience in the practice of medicine in Louisiana had said to him that the prognosis in the cases referred to by Dr. Jacobi and Dr. Loomis, occurring in children, was entirely different from that which he heard while in New York—namely, that these persons succumbed early in life to the cardiac disease. Whether or not climatic conditions influenced the course of the disease he was not prepared to say.

Dr. J. C. Peters had no doubt that many children were frightened to death by physicians. He had become convinced that one who had been as long in the practice of medicine as he had, must unlearn a great many things which were learned in previous years.

Dr. R. C. M. Page was satisfied that almost any heart-murmur might be heard at nearly any point over the chest. Certainly the areas of conduction as laid down in the books were to be taken with some exceptions.

Dr. N. E. Brill spoke of the presence of murmur in chorea without change in the endocardium, and thought such cases could be readily explained by lack of proper nervous supply, the same as excessive muscular exercise, as in college students who induged excessively in athletic sports not infrequently produced functional disturbance of the heart.

Dr. Jacobi thought that Dr. Brill's suggestion was quite correct. In a number of cases of chorea there might be heard a cardiac murmur for half a day, when it would disappear, to return, and, finally, disappear entirely. He had always attributed the murmur in such cases to the fact that the heart got fatigued and contracted irregularly.

Dr. A. H. Smith had frequently been led to ask himself the question whether all cases of heart disease

WHICH OCCUR IN ADVANCED LIFE

were not really revivals of an old condition.

Dr. Loomis referred to the case of a prominent physician who came into his office not long ago and said that he was unable to go upstairs as he had been accustomed to do. On listening to his chest a cardiac murmur was heard, the heart was also dilated, and there was feeble cardiac impulse. The patient said that he had a murmur when young which followed rheumatism, but that he had not experienced any inconvenience with his heart until rather recently.

The Chairman said that one important practical question to be decided was whether these children should be allowed to engage in athletic sports, such as the common sports of school-life and boyhood. So far as his experience went, indulgence in them was beneficial, when regulated by the character of the lesion and the general condition of the patient.

Dr. Kinnicutt said that graduated physical exercise largely entered into the present method of treatment of organic disease of the heart in Germany, and the best results were claimed for it. He personally believed that carefully regulated athletic sports were not contraindicated in many cases.

Dr. Delafield regarded the point made by Dr. Loomis concerning the presence of cardiac murmur in children, and the development of serious symptoms when the degenerative period in life was reached, as well taken and one that was true, yet he

DOUBTED IF THAT WERE THE ENTIRE TRUTH.

It seemed to him that the question took a rather wider range than that. It was unquestionably true that children who had had endocarditis did very well for many years, and when they got old cardiac disease developed. On the other hand, it was equally true that a great many developed endocarditis when adults, and went on many years, until they reached the same period in life and then they began to suffer.

The same was true of pulmonary emphysema, and also of the atrophic form of chronic Bright's disease. Patients suffering from either of those affections might go on in fairly good health until they reached the same period in life, and then have serious trouble.

Did not all this mean that persons who suffer from this particular form of chronic inflammation might, if the inflammation had developed slowly enough, experience no trouble until they reached this hazardous period in life, when the same lesion would cause a great deal of trouble? He was rather disposed to place these children's cases not by themselves, but regard them as another part of the same general rule.

Dr. A. H. Smith thought that so long as the muscular exercise could be graded it might answer to allow children with cardiac disease to participate in school sports, but he would be unwilling to allow a boy with cardiac insufficiency to take part in rowing matches, etc., where he would be obliged to go through with his duty at all hazards.

The Chairman referred to five men who did well as the result of engaging in the ordinary sports of college, but not rowing matches or violent games.

Dr. Kinnicutt said that by athletic sports he meant the usual outdoor sports of children and youths. He certainly would forbid a patient suffering from organic disease of the heart to engage in the athletic *contests* of the present day.

Dr. Heinemam said that the particular point which he wished to reach was an agreement as to what shall constitute a cardiac murmur. He thought it would be agreed to that only such sounds should be considered as cardiac murmurs as were *adventitious*, and not changed heart-sounds. He then spoke of thrill—the diagnostic value of which he regarded as questionable. He also referred to the case of a longshoreman, sixty-nine years of age, who carried a murmur fifty-two years without special inconvenience. In the light of such cases the significance of cardiac murmurs must still remain an open question. An important point to be decided was, when shall we say that a given sound is not an accentuation, but a cardiac murmur, and when not a murmur, but an accentuation? He thought it probable that in solving the problem it would become necessary to invoke the aid of the sphygmograph and other instruments of precision.

The Section then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 9, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. J. S. Thacher, from the Committee on Microscopy, reported that the ovarian tumor presented by Dr. A. P. Dudley, September 28, 1887, showed a stroma of connective tissue quite rich in cells in places, with many alveoli, in some of which could be seen a lining of cylindrical epithelium. The tissue therefore resembled that of a

MULTILOCULAR OVARIAN CYST.

Dr. Hodenpyl presented, in behalf of a candidate, a specimen of *aneurism of the descending portion of the arch of the aorta.*

Dr. J. S. Thacher presented, in behalf of a candidate, specimens of blood which showed the *plasmoideum malariæ.*

Dr. Lewis Hall Savre presented, in behalf of a candidate, a specimen of *abdominal tumor*, which was referred to the Committee on Microscopy.

Dr. Mary Dixon Jones presented a microscopic section which showed the lesions of

CHRONIC CERVICITIS,

and she raised the question whether the changes affecting the smooth muscle-fibres and the presence of connective tissue might not be causative factors in cervical lacerations.

Dr. Jones also presented four specimens of

TUBES AND OVARIES,

with the history of suffering by the patients and benefit by the operation. In one case there were extensive adhesions; in one, no adhesions; in one the patient ceased menstruating at the age of twenty-five; in three cases the women had not borne children, and in the other two children.

Dr. Jones raised the question of the length of the abdominal incision which was best to be adopted.

Dr. Wackerhagen presented the amputated limb in a case of

SENILE GANGRENE, INVOLVING THE POSTERIOR REGION OF THE LEFT ANKLE-JOINT,

occurring in the person of Mr. R——, a native of the United States, seventy-eight years of age, and by occupation a farmer. His health had always been good until last April, when he noticed a small, dark-colored spot upon the lower and posterior part of the left ankle. The discoloration gradually spread to both sides of the tendo Achillis, and upward for about three inches above the posterior tuberosity of the os calcis, where the line of demarcation formed, leaving a slough which involved the posterior portion of the calcaneum, the tendo Achillis, and adjoining soft parts. His general health was good. This was his condition when he first saw him, with Dr. J. E. Gregory, on October 13th.

Tonics and nourishing diet, with moderate stimulation, were prescribed. On the day following, the gangrenous slough was cut away with scissors, and the surface thoroughly washed with sublimate solution—1 to 2,000—and dressed with iodoform gauze. These dressings were changed daily. On Tuesday, October 18th, a healthy granulating surface having appeared, the sublimate irrigations were discontinued, and a two per cent. solution of carbolic acid was substituted. On Thursday, October 20th, the granulation appeared of a dusky hue, and as the foot was becoming quite painful it was determined to accede to his wishes, he being anxious to have the affected limb removed.

Amputation was performed on Saturday, October 22d, at the lower third of the thigh, by the circular method.

The femoral vein was pouched, and its walls were so fragile that the slight effort in separating it from adjoining structures caused it to tear. Calcareous deposits were found in the walls of the femoral artery at and above the place where it was divided, and it was found necessary to follow it up for a distance of nearly two and one-half inches before a suitable place was reached for the application of the ligature. All vessels were ligated before the removal of Esmarch's bandage; but as there was some oozing from the cut ends of the muscles it was found necessary to apply hot water to the stump, after the method of Dr. Varick. This stopped all bleeding in a few minutes, when the drainage-tubes were placed and the short skin-flaps were united with silk-worm gut. Sublimate irrigation was used very sparingly, boro-salicylic solution being substituted for it during the operation. The edges of the sutured wound were slightly sprinkled with iodoform. Having applied the rubber protective, the stump was dressed with five per cent. iodoform gauze, and covered with sublimate gauze; over this was placed carbolized cotton, and over all a large, fine-wool cushion.

The patient came out of the anæsthesia in good condition, without indication of shock or prostration. He was in a cheerful state of mind, and continued to improve until Thursday, October 27th, when the pulse increased in frequency (90), and the temperature, which had been normal, increased to 100⅖° F.; the temperature, however, decreased on the following morning to 99½° F., but the pulse increased to 100. The tongue became furred, and there was some disposition to diarrhœa. This was readily checked with bismuth.

On Friday, October 28th, the temperature again rose to 100⅗° F., and the pulse to 110. On the following morning the dressings were changed for the first time, and we were gratified to note that the wound had almost completely united, and the stump was in every respect in excellent condition. The patient was also generally improved, and so expressed himself. About eight o'clock the same evening the nurse telephoned to Dr. Gregory, who found Mr. R—— rapidly failing. There were involuntary discharges from rectum and bladder. He died at nine o'clock, with symptoms of heart-failure. Post-mortem examination was not permitted.

The specimen showed

CALCIFICATION OF ALL THE ARTERIES, ANTERIOR AND POSTERIOR, TIBIAL, PERONEAL, AND POPLITEAL.

Dr. Ira Van Gieson presented specimens of

MULTIPLE CAVERNOUS ANGIOMATA OF THE LIVER,

removed from the body of a middle-aged woman. In the liver there were about thirty tumors, varying in size from 3 mm. to 1½ ctm. in diameter. The tumors were of a deep-red color, sharply outlined from the adjacent liver-tissue, and were composed of anastomosing trabeculæ and laminæ inclosing irregular-shaped larger and smaller spaces filled with blood. The surface of the liver was retracted over the superficially situated masses. Some of the tumors were surrounded and intermingled with dense white areas consisting of connective tissue moderately well supplied with small capillaries.

Dr. Van Gieson also presented a specimen of

NEUROMA OF THE SCIATIC NERVE AFTER AMPUTATION OF THE THIGH.

The nodule measured one-half by one-fourth of an inch.

The best illustration and description which he had seen of these tumors was by Krauser and Friedländer, who had described the changes in the peripheral nerves, and in the spinal cord, studied particularly in a case of amputation of the arm, where the nonules were found to be composed almost exclusively of nerve-fibres.

The theory advanced was, that after the nerve was divided in amputation the motor fibres perhaps seek to join the peripheral segment of the nerve which has been removed, and in their wandering, as it were, push against the resisting tissues and form nodules on the proximal end of the nerve.

The President remarked that one point of interest in Dr. Van Gieson's specimen of angioma was the large number of little tumors.

Dr. Ferguson had not seen more than four or five of these growths in a single liver. The largest he had seen was about two and a quarter inches in diameter.

Dr. Carpenter had not found more than three or four; and

Dr. W. H. Porter had not seen more than four or five, and they had been small in every case except one, where the whole liver was involved.

The President referred to a case in which the growth projected from the liver to about the size of the pregnant uterus, and was removed by operation, but with what result was not stated in the report.

Dr. Frank Ferguson presented a

MICROSCOPIC SECTION OF THE STOMACH, SHOWING A RUPTURED ARTERY WITH SUBMUCOSA AND ITS ACCOMPANYING VEIN.

It was from the body of a woman, twenty two years of age, who died of septic parotiditis, developing in the state of exhaustion due to loss of blood, which showed itself by profuse hæmatemesis and the characteristic evacuations from the bowels. The first hemorrhage occurred three months after an attack of black measles, from which the patient apparently recovered completely.

The case had been reported by Dr. Abbe, in the *New York Medical Journal*, October 29, 1887.

The autopsy was made by Dr. Ferguson, and showed, in addition to marked anæmia of all the organs, a stomach which was normal in size and location; the cardiac and pyloric orifices were normal in size and perfectly free. The mucous membrane was smooth and very pale in color. In the posterior wall, 6 ctm. from the œsophageal orifice, and just to the right of a line drawn parallel to the œsophagus, was an apparent loss of the mucous surface, circular in shape and 6 mm. in diameter. In its centre was a hard, nipple-shaped elevation, and beside this elevation, extending transversely across the implicated area, was a vessel with thin walls partially filled with blood. There was no elevation of the edges of the area, and by the unaided eye it could not be identified as an ulcer. Microscopic examination of the area showed a total loss of the mucous membrane to the extent of the measurements given above. At the base of this ulcer were seen an artery and vein of considerable size.

THE WALLS OF THE VEIN WERE EVERYWHERE INTACT.

The hard, nipple-like elevation, already described, was the ruptured wall of an artery. Sections carried along through the entire ulcer showed a rupture of the artery involving one-half of its wall; the other half showed no evidence of disease. A mass of fibrin and blood clung to the ruptured wall, and for a short distance on either side of the rupture the wall was split up and contained fibrin and blood. There was a zone of small round cells surrounding the ulcer, and at the bottom the capillaries were filled with blood and the round cells of inflammation infiltrated the connective tissue. Sections made in other parts of the stomach revealed no lesion of its coats or vessels.

Dr. Ferguson also presented specimens which illustrated

CHRONIC DIFFUSE NEPHRITIS—CARDIAC HYPERTROPHY—LESIONS OF THE CEREBRAL VESSELS—CEREBRAL HEMORRHAGE.

They were removed from the body of a man, fifty-five years of age, a native of Ireland, and by occupation a shoemaker, who was admitted to the New York Hospital, with hernia, on October 31, 1887.

On November 2d he became stupid, breathed stertorous at times, his right pupil was a little larger than the left, and there was impaired sensibility of the right side, but no paralysis. His pulse was slow, strong, and full, of very high tension, and his peripheral arteries were atheromatous and tortuous. He had a well-marked *arcus senilis*. He had neither convulsions nor elevation of temperature. He had paralysis of motion and sensation on the right side. His respiration became Cheyne-Stokes in character. His urine was amber-colored, acid, 1.012, and contained fifty per cent. of albumen to the column, with hyaline, granular, and epithelial casts. His coma gradually deepened, his temperature rose to 103° F., on the afternoon of the 6th. His respiration became more shallow, his pulse more feeble, and he died on the 7th, at 3 A.M.

The autopsy revealed a hemorrhage as large as an ordinary hen's egg, destroying the ganglia at the base of the left cerebral hemisphere. There was no rupture of the floor of the left ventricle. There were numerous smaller extravasations in the neighborhood of the large hemorrhage. The convolutions were distinctly flattened.

THE VESSELS AT THE BASE WERE DILATED AND MODERATELY ATHEROMATOUS.

The smaller vessels and capillaries in the neighborhood of the hemorrhages showed extensive fatty degeneration of their walls, and in many places the perivascular spaces were filled with large granular cells. In places these granular bodies were also seen within the wall of the vessels.

The walls of the smaller arteries were split up, in places, into layers by small round and spindle-shaped cells, rendering the diameter of some of the vessels six to eight times their natural size. While in many places aneurismal dilatation of the smaller arteries was found, there were no distinct miliary aneurisms noticed. These arteries were shown under the microscope, both stained and unstained.

The kidneys were slightly larger than normal. Their capsules were not adherent. Their surfaces were smooth, their cortices were swollen, and their markings were indistinct. The cortex of each organ contained a very great deal of fat.

The renal arteries were dilated and tortuous. Under the microscope their walls were seen greatly thickened. The tubes of the cortex and pyramids were dilated and contained fat. There was much increase in the fibrous tissue.

The heart was greatly hypertrophied. All its valves seemed competent. The muscular tissue was fatty and anæmic. The coronary arteries were dilated and tortuous, but not atheromatous. Under the microscope there was seen increase in the interstitial fat, and the muscle-cells were swollen, granular, and fatty.

FRACTURE OF THE CERVICAL VERTEBRÆ—HEMORRHAGE IN THE SUBSTANCE OF THE SPINAL CORD.

DR. W. H. PORTER presented specimens taken from the body of a man, twenty-eight years of age, who accidentally fell down one flight of stairs and broke off the posterior arches of the third, fourth, fifth, and sixth cervical vertebræ, and at the same time fractured, anteroposteriorly, the bodies of two of these vertebræ.

When the ambulance surgeon reached the spot he found the patient partially paralyzed. He took hold of his head and raised it upward. While doing so he felt the bones crepitate, and the paresis was so much improved that during the next twenty-four hours there was comparatively little loss of sensation and motion. On the second day the paresis returned, gradually increased, and the patient died from paralysis of the diaphragm.

At the autopsy there was found only a slight amount of hemorrhage in the soft parts about the vertebral column, no hemorrhage between the dura mater and the bone, and none

BETWEEN THE PIA MATER AND THE CORD.

But into the substance of the cord there was hemorrhage, in the space covered by two or three vertebræ, which caused the death of the patient.

One interesting point in the case was the fact that there was little or no hemorrhage outside of the substance of the spinal cord. There were apparently multiple hemorrhages entirely within the substance of the cord.

INTRALOBULAR CIRRHOSIS OF THE LIVER—CHRONIC SPLENITIS.

Dr. Porter also presented specimens with the following history: They were taken from the body of a woman, forty years of age, without the history of syphilis or alcoholism. When admitted to the hospital she had marked dyspnœa, and her abdomen was full of fluid. She was tapped at once, and three gallons of fluid were removed. Stimulants and diaphoretics were administered, the general œdema disappeared entirely, and the condition of the patient improved.

Physical examination then revealed double aortic and mitral lesions. The ascites only returned, and the patient died on account of the extensive accumulation of fluid in the abdominal cavity.

The autopsy revealed aortic and mitral insufficiency. There were five gallons of fluid in the abdomen. The spleen was very much enlarged, and its capsule was dense and very much thickened. It weighed twenty-two ounces. The liver was very markedly atrophied. It weighed twenty-nine ounces. Microscopic examination showed intralobular cirrhosis, with pigmentation of the hepatic cells. The central veins were not involved. The kidneys showed the lesions of chronic diffuse nephritis.

SEPTIC PERITONITIS AND ENDOCARDITIS.

DR. J. LEWIS SMITH presented specimens from a newborn infant, with the following history:

Lizzie C——, a primipara, was confined on September 21, 1887. Her labor was normal, lasting five hours, and there was nothing unusual in her case before and after her confinement. The baby, a female, was normally developed, weighing eight pounds and one ounce. She had natural evacuations, took the breast readily, and seemed entirely well until the afternoon of September 28th, when she became restless and refused the breast; rectal temperature 101.4° F.; respiration accelerated markedly, and accompanied by an expiratory moan. On September 29th, A.M., temperature 103.4° F.; was very restless; respiration as before; took milk from a spoon; evening temperature 103.6° F. On September 30th, temperature 104° F.; vomiting, restless; respiration 56, and accompanied by an *expiratory moan* when she was moved; pulse counted with difficulty, but not less than 200; slight twitching of extremities on left side. There was no cough, and a careful examination of the chest by percussion and auscultation gave a negative result. It had been maintained by some writers that the *expiratory moan* indicated the presence of some pulmonary disease, as pneumonia or pleurisy, but neither were present in this case. The abdomen was prominent, or distended, soft, not hard, and it gave a dull percussion-sound over every part. Dr. Smith was uncertain, from the feebleness of the child, whether pressure upon it gave pain. The diagnosis of peritonitis, probably of septic origin, was made. On September 30th, evening temperature 104.4° F.; the patient was sinking. Death occurred at 11.15 P.M.

Autopsy, by Dr. E. C. Wendt: Body moderately emaciated; slight rigor mortis. About three ounces of seropurulent fluid, containing abundant flakes of fibrin, escaped from the abdominal cavity. All the abdominal organs were covered by a thick layer of fibrin; liver and spleen

completely covered by it, and intestines loosely matted together by it. Left lobe of liver much enlarged, touching the spleen and left kidney; appearance of a section of the liver normal. Umbilical vein pervious; it contained clots of blood and dirty-looking pus, but the umbilicus was of normal appearance and cicatrized. The brain and its meninges seemed normal, unless a little congested. The posterior cusp of the aortic valve was thickened and rigid, and attached to it was a fibrinous mass. The appearance indicated

A LOCALIZED ENDOCARDITIS

at and around the valve; otherwise the thoracic organs seemed normal.

A microscopic examination of the organs was made by Dr. Frank Grauer, of Carnegie Laboratory, who found no evidence of inflammation in the umbilical vein, but thinks, from the history and appearance, that it contained septic matter from which the peritonitis and endocarditis originated of which the infant died. The liver was not only swollen, but under the microscope the peculiar cloudy appearance characteristic of parenchymatous inflammation was observed. The kidneys were normal, the straight tubules containing, as is common in the new-born, beautiful urate-of-sodium crystals. The cardiac muscular fibres were distinctly granular in places. Dr. Grauer's description of the state of the aortic valve was as follows: "There was slight endocarditis, situated at one of the segments of the aortic valve, to which was attached a small thrombus."

SEPTICÆMIA OF THE NEW-BORN

is one of the most severe and fatal maladies of early life. It appears to originate, ordinarily, from decomposing thrombi in the umbilical vein, in which multitudes of micrococci are developed. These organisms, with fragments of thrombi undergoing decomposition, pass along the umbilical vein to its branches which enter the liver, and to the ductus venosus, and finally entering the ascending vena cava, produce a general systemic infection. Disintegrating particles of the fibrinous clots, loaded with micrococci intercepted in the organs, cause embolisms and septic inflammations. Septic inflammations, whether occurring in the interior of organs or upon one of the surfaces as in this case, in which a general peritonitis was developed, are intractable and usually fatal.

Treatment.—It is obviously very important that strict cleanliness be observed in the treatment of the umbilicus of the new-born, since it is supposed that the entrance of microbes through the umbilicus into the umbilical vein causes the putrefactive changes which produce the septicæmia. Care should be taken that the water and sponges employed in bathing the child be free from impurities, that no dirt or foul substance lodge in the umbilicus, and that the abdominal bandage be entirely clean. It might be well to dust the umbilicus with some antiseptic powder, as a mixture of bismuth and iodoform, as a preventive measure.

Dr H. J. Boldt referred to the report of a similar case in one of the German journals, in which the writer described it as one of septic peritonitis due to suppuration of the umbilical vein.

The President remarked that in a very considerable number of cases of acute ulcerative endocarditis, microorganisms were present, particularly the staphylococcus aureus and albus, which readily caused phlebitis as well as peritonitis. He thought there was a possible, perhaps probable, relation between the inflammation of the umbilical vein, in Dr. Smith's case, and the peritonitis and endocarditis, and that the external appearance of the umbilicus did not preclude the existence and progress of phlebitis.

The President presented specimens of

CIRRHOSIS OF THE LIVER, WITH ATROPHY AND CHRONIC INDURATIVE SPLENITIS,

which were interesting in connection with Dr. Porter's specimens. The history of the case was meagre, and for what there was of it he was indebted to Dr. Hubbard, House Physician, First Medical Division in Bellevue Hospital. The patient was an unknown man, thirty-seven years of age, and a native of Germany. On October 18, 1887, he was transferred from the Insane Pavilion to the Hospital. His mental condition prevented the obtaining of any reliable history from him, and he had no friends.

On admission there were moist râles over both lungs. The upper line of hepatic dulness began at the lower border of the third rib in the mammary line. There was marked ascites, and there was some œdema of the feet and legs. After the removal of two hundred ounces of clear serous fluid from the abdominal cavity the area of hepatic dulness seemed to be about normal, while that of the spleen was markedly increased. Seventeen days afterward he was tapped again, and three hundred and thirty-six ounces of cloudy serum were withdrawn. After that his strength failed rapidly, and his temperature, which had been normal, rose, two days before death, to 101½° F., and he died cyanosed on November 8th.

Autopsy.—The peritoneal cavity contained about two litres of turbid reddish serum. The diaphragm on both sides was at the level of the third rib. Heart and lungs normal. Liver was small; its right lobe so much diminished in size as to about equal the left, so that the whole organ was ovoidal in shape. It weighed 1,530 grammes, and measured 25 ctm. in length, 12 ctm. in width at the widest part, and 7 ctm. in thickness. The surface was coarsely nodular, and from its lower surface projected several polypoid and globular masses of liver-tissue which had been constricted and forced out by the new formation of connective tissue. The cut surface showed larger and smaller masses of yellowish liver-parenchyma surrounded by bands of new-formed fibrous connective tissue. The spleen was large, dark, and firm, and its cut surface traversed by slender bands of new-formed connective tissue. The capsule was irregularly thickened. The organ weighed 1,300 grammes, and measured 25 ctm. in length, 12 ctm. in width, and 7 ctm. in thickness. The kidneys and other abdominal viscera were apparently normal.

He presented these specimens, showing not uncommon lesions, because the lesions were both typical and excessive, and because the changes in the liver and spleen had brought these two organs, naturally so dissimilar, to very nearly the same size.

The Society then went into executive session.

Anecdote of Dr. Golding Bird.—Dr. Routh tells the following: "I well remember a conversation I had with the late Dr. Golding Bird a few weeks before his death. He was then in the zenith of his popularity, and recognized by all as one of the ablest of our London physicians. I called upon him one morning with a relative to consult him. Several other medical men preceded me. His rooms were full, and I had to wait three hours ere I could obtain admission to his study and consult him about the case. I congratulated him on his success in practice. 'Yes,' he said to me, 'you are right; but I wish, nevertheless, to make your remark a text for a little parting advice. You see me at a little over forty in full practice, my rooms are full, and I am making my several thousands per annum (I think he said seven), and if I die to-morrow I do not leave as many hundreds to my family. All this I have done by sheer perseverance, unceasing hard work, and no holiday. But I am to-day a wreck. I have fatal disease of the heart, the result of anxiety and hard work. I know I cannot live many months, and my parting advice to you is this: Never mind at what loss, take your six weeks' holidays. It may delay your success, but it will insure its development. Otherwise you will find yourself at my age a prosperous practitioner, but a dying old man.' Six months after this conversation he had put off this earthly tabernacle."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BROWN LECTURES ON RABIES—THE GENERAL MEDICAL COUNCIL—REMOVAL OF TUBERCULAR MOVABLE KIDNEY—MEDICAL SOCIETY OF LONDON—THE GERMAN CROWN PRINCE—SIR WILLIAM GULL.

LONDON, November 29, 1887.

YESTERDAY afternoon, at the University of London, Professor Horsley commenced his course of "Brown Lectures" for the present year. His audience was rather scanty, only numbering some sixteen souls, but the lectures will in due time be published in the press and thus reach a larger circle. His subject for the present year is "Rabies, or Hydrophobia," and yesterday afternoon he announced his intention of making the lectures somewhat more popular than heretofore. Commencing with the history of the disease, he traced it back to Hippocrates and Celsus, to both of whom, he said, the disease was known. In this country it had been shown (by Dr. Fleming) that it was known in Anglo-Saxon times.

As to its distribution, it was more common in London and towns than in country places, and by means of maps, colored to show the localities where the most cases had occurred, it was shown to be most active in the Midland districts of England. In both Scotland and Wales it was almost unknown. The frequency of the disorder had largely increased of late years.

Professor Horsley attributed the partial limitation of rabies to the Midland counties to the fact that they were separated from the surrounding districts by wide rivers and mountainous regions. On some of the borders, also, there were extensive sheep-walks, and the shepherds were very prone to kill any stray dog which came in their way, for fear of its injuring any of the lambs or ewes. Proceeding next to consider the nature of the poison, it was pointed out that the long period of incubation—seldom less than six weeks—negatived the idea of a simple chemical poison. The view now accepted was that it was a parasitic micro-organism, though it had not yet been found possible to isolate it. A Swiss observer had asserted that he had been able, by a peculiar process of staining, to determine the presence of micrococci in the spinal cord, but his observations had been found to be fallacious, and the so-called micrococci to consist of granules of hæmatoxylin. Mr. Dowdeswell had since been more successful than the Swiss observer, and had been able to prove the presence of micrococci in the spinal lesions, but had been unable to cultivate them. The poison acted with special force on the brain and nervous centres. The salivary glands were also specially attacked. The saliva, milk, and urine from a rabid animal had all been proved to contain the poison. Pasteur's method of experimental inoculation was that at present followed. This consisted in placing some of the diseased tissue in a sterilized broth or other medium, and then injecting a little of the latter on to the surface of the brain of an animal. Where antiseptic precautions had not been used, many of the animals thus experimented on had perished from septicæmia, death often occurring within two days. This explained early failures, and also the extraordinary statements of some foreign observers, that a decoction of brain-tissue from any healthy animal would, if placed on the surface of the brain of an animal, cause rabies. Saliva, being a septic fluid to begin with, was not satisfactory to employ for such experiments, but both milk and urine from a rabid animal had been (with proper precautions) injected on to the surface of the brain of animals and rabies had followed.

During the past week the General Medical Council has met again, and has held rather a drastic session. Two medical men have been removed from the Register; the one for misdemeanor, having been sentenced to two years at hard labor for a libel, the other for "infamous conduct in a professional respect" in connection with a divorce case. The question of unqualified assistants came up again, and one medical man was brought up before the Council for having (by means of an unqualified assistant) conducted a practice eighteen miles away from his house. He was let off with a censure, on promising to discontinue the practice. The case of the author of a book called "The Wife's Handbook" was also considered. In the book are advocated Malthusian views, and advertisements are inserted of various appliances for preventing conception. It had been suggested that the book was indecent and immoral, and that its publication was "infamous conduct in a professional respect." The case of an advertising dentist will also occupy the Council during their present session. This gentleman had his dental diploma taken away from him by the Edinburgh College of Surgeons, on the ground that he continued to advertise in defiance of their rules. The General Medical Council thereupon promptly removed his name from the Dental Register. Mr. Partridge, however, contended that as he had been in practice before the Dental Act was passed, he was, in accordance with the provisions of that act, entitled to be on the Dental Register without having any dental diploma. A court of law has confirmed the view taken by Mr. Partridge, and the Medical Council will now have the mortification of being compelled to replace his name on the Dental Register.

At the last meeting of the Medical and Chirurgical Society, Mr. Warrington Haward related a case in which he had made an abdominal incision and removed a movable kidney which had undergone scrofulous suppuration. The patient unfortunately died in forty-four hours, but the post-mortem examination showed that the other kidney was healthy (though greatly congested), and that there was a complete absence of disease in the rest of the body. Dr. Ord observed that he would be very slow to advise removal of the kidney, unless he were sure the other kidney was sound. He suggested that this could be ascertained by determining the percentage of urea in the urine from the ureter of the (presumably) sound kidney. Mr. Haward remarked that it was difficult to decide as to the condition of the other kidney, even by an examination of the urine, and palpation would not decide the point.

At last week's meeting of the Medical Society of London, the chief feature was the reading of an elaborate paper, by Dr. David Ferrier, F.R.S., describing the symptoms and post-mortem appearances of several cases of hemi-anæsthesia. Mr. Knowsley Thornton also read a paper describing two cases in which he had successfully performed cholecystotomy for gall-stones impacted, in the one case in the common duct, in the other in the common and cystic ducts.

The case of the German crown prince continues to excite the most lively interest and sympathy, both in professional and lay circles. In the former little doubt is expressed that the new growth is cancer, and that a fatal termination is to be looked forward to at no very distant date. In the discussions which have taken place on operations for malignant disease of the larynx, I am surprised that more stress has not been laid on Dr. Foulis' case. In 1877 this gentleman (now deceased) removed the larynx for sarcoma, and the operation was completely successful, though his patient died a year later from phthisis. I saw Dr. Foulis' patient in 1877 after the operation, and he was able to speak in a monotone by the aid of an artificial larynx which had been made for him.

Sir William Gull has returned to London, and is much better.

THE PLACE OF MEETING OF THE TENTH INTERNATIONAL CONGRESS.

To the Editor of The Medical Record.

Sir: As the American member of the committee of the Ninth International Congress which was appointed to select the place of meeting for the Tenth Congress, to be held in 1890, I may be permitted to supplement your editorial notice, in your issue of the 19th ult., of the declarations by the editor of the *Journal de Médecine de Paris*, under date of September 25th, that "through the influence of Professor A. Martin, Berlin was selected as the place of meeting for the next Congress," and that "the American physicians have bent under the Prussian yoke," with the following:

1. The United States were represented on that committee, as was each nationality having membership in the Congress, by a single member.

2. The representative of France, appointed on that committee, Dr. Landolt, did not attend its session.

3. Senator Semmola, of Italy, was elected chairman of the committee, and he took occasion, in returning thanks, to prefer Berlin as the place of next meeting of the Congress.

4. I followed with a statement that as the first Congress had been convened in France (Paris, 1867), the second in Italy (Florence, 1869), the third in Austria (Vienna, 1873), the fourth in Belgium (Brussels, 1875), the fifth in Switzerland (Geneva, 1877), the sixth in Holland (Amsterdam, 1879), the seventh in Great Britain (London, 1881), the eighth in Denmark (Copenhagen, 1884), and the ninth in the United States (Washington, 1887), there remained Germany and Russia as having an *à priori* claim to the selection; and that as preference had been given to Washington over Berlin at the Eighth Congress at Copenhagen, where the place of meeting of the ninth was determined, it seemed eminently proper that Berlin should now be chosen, and that the American representative should second the nomination made by the representative from Italy, which I then did.

5. Professor Reyher, the representative of Russia upon the committee, thereupon rose and admitted the justice of the preference given to Berlin, and in doing so said that he wished to put on record that by this acquiescence he established a claim to have the Eleventh Congress meet at St. Petersburg, in 1893.

6. Professor Martin, the member of the committee from Germany, upon this rose to express the gratification himself and colleagues would experience if Berlin were made the place of meeting of the Tenth Congress.

7. The representative from Switzerland, Dr. Cordés, thereupon proposed that the Tenth Congress should be convened at Paris, advancing as a chief reason that the intended centennial celebration at that city, in 1889, would make time and place especially appropriate for such an international reunion.

8. Several members of the committee replied that as a triennial period had been practically established, the meeting of the Congress in 1890 could not be coincident with the celebration of 1889, and that, consequently, this argument for holding a second Congress in France, to the exclusion of Germany and Russia, where none had yet been held, had manifestly no foundation.

9. The voting was by inscription, and when the secretary of the committee, the representative from Roumania (Dr. Monolescu), read the list, it was found that every member had voted for Berlin, excepting only the representative of Switzerland, whose vote was recorded for Paris.

10. The result was reported to the General Session of the Congress on the following day, by the chairman of the committee, and was unanimously approved, without objection or protest. Consequently, in the face of this ratification by the twenty-three or more nationalities represented in the Congress, it is difficult to understand how the editor of the *Journal de Médecine de Paris* can assert that "the next meeting will not be an International Congress, but merely a German reunion."

As for personal solicitation, I have further to state that Rome was the only city in whose interest I was strongly approached; but as the Italian representative himself proposed Berlin, for the twofold reason, that a Congress had already been held in Italy, and that Berlin had been so strongly advocated at Copenhagen and set aside for Washington, I felt it my duty to acquiesce in his view, and in doing so I certainly do not feel that I "have bent under the Prussian yoke," nor do I believe that MM. Le Fort, Récamier, Landolt, Apostoli, or any other of the eminent members of the Congress from France, nor Dr. Cordés, of Geneva, who so earnestly advocated the selection of Paris, have ever countenanced any such declaration.

Very respectfully, your obedient servant,

Albert L. Gihon,
Medical Director, United States Navy.

Mare Island, Cal., November 24, 1887.

THE RECOGNITION AND TREATMENT OF INSUFFICIENCY OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In looking over, recently, your report of the proceedings of the International Congress at Washington, I find in your issue of September 10th, p. 343, the following statement:

"Dr. George F. Stevens, of New York, read a paper on 'Some Important Problems Respecting Insufficiency of the Ocular Muscles.' He said that anomalies of the ocular muscles were of as frequent occurrence as those of refraction and accommodation, while the literature of the subject was very scanty, and what existed would lead one to infer that only one of the muscles was liable to insufficiency—the internus—while the deviations in other directions had been ignored or barely mentioned.

"The object of the paper was stated to be to suggest certain problems, rather than to explain apparent contradictions. For instance, a case showed, with a prism over one eye, insufficiency of the externi of 8° at twenty feet, and at one foot insufficiency of the interni of 10°. There was an adducting power of 50°. Now, there could not be an insufficiency of both interni and externi at the same time. Another case, with the prism eliminated from the question, had diplopia, homonymous, of 4° at twenty feet, and, crossed, of 5° at two feet. Here seems to be a contradiction of results and a problem to explain."

In justice to my illustrious predecessors whose works have already become classical, and in justice to my *confrères* who are, and have been for so many years, carrying out the principles inculcated and practised by them, I should like to say that it has not appeared to me that the literature was very scanty, nor that what existed would lead one to infer that only one of the muscles was liable to insufficiency. Moreover, to my certain knowledge, all the oculists of this city and of the country, who have any pretensions to a moderate degree of proficiency, have, for the past twenty years, made examinations and prescribed prisms for insufficiency of all the recti muscles, including also the oblique muscles, and have likewise, when the proper occasion has arisen, operated upon, not only the internal, but also the superior, exterior, and inferior recti. It is true, however, that they have not applied these operations to the cure of advancing glaucoma, diplopia from tumors in the orbit, progressive spinal disease, and epilepsy.

As to the statement that "there could not be insufficiency of both the interni and externi at the same time," the first comprehensive text-book which one is apt to take up says: "There has been a great deal said of the insufficiency of the internal straight muscles (see Strabis-

mus divergens), but insufficiency of the external straight muscles of the eyes has also been observed in connection with asthenopic troubles (Knapp, Loring), and even a simultaneous insufficiency of the internal and external straight muscles (Kugel)." [1] Noyes, in "Diseases of the Eye," also says: "For instance, we may have insufficiency of the externi for distance, and of the interni for the near" (p. 94, also see p. 91).

As a matter of fact, insufficiency of both the external and internal recti at the same time, though rare in normal eyes, is not uncommon in the higher degrees of myopia, and in excessive degrees, where binocular single vision runs through the range of relative accommodation, it is the rule. It depends on a physiological fact, so old that it seems in this case to be forgotten, that the equilibrium of the recti muscles, taken as a whole, is not a condition of parallelism of the axes, but of a moderate degree of convergence.

As to these subjects being "important problems to be explained," they are already well understood by the ordinary student of ophthalmology.

Yours respectfully,

EDWARD LORING, M.D.

128 MADISON AVENUE.

ANTIFEBRIN AND ANTIPYRIN AS HYPNOTICS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Several months ago I began the use of antifebrin and antipyrin as hypnotics, pure and simple. Though these drugs have been recommended for various morbid conditions, especially for headaches and for the relief of pain in general, they have not, so far as I have been able to discover, been tried in simple insomnia. In one of your late issues, to be sure, there is a communication headed "Antipyrin in Insomnia," but a perusal of the article shows that certain morbid conditions existed in the cases mentioned, and that sleep was obtained by the *modification* of some of these conditions by the remedies employed. Upon the day that this communication was published, I made known my experiments to Dr. Andrew H. Smith, and asked him to test the subject himself; neither of us had received that issue of THE RECORD at that time. I was induced to try these drugs for the purpose named by noticing that antipyrin caused a tendency to sleep when given for the relief of headache. My first experiments were made in the case of a highly neurotic lady, who had suffered a severe shock in the loss by suicide of her favorite son. She had been unable to sleep for many months unless under the influence of large and increasing doses of bromide of potassium, and the sleep that was in this way obtained was short and restless. She was ordered fifteen-grain doses of antipyrin, and under the influence of these the nurse at once reported longer and more refreshing sleep. Still, although these results were relatively very encouraging, they were not altogether satisfactory, and I began the use of ten-, and afterward fifteen-grain doses of antifebrin administered in capsules. Under the influence of these she slept for five and six hours at a time, a comfort that she had not known for years. There were no after-effects. She has been using the capsules now for about three months, although in her case there seems also to have been a curative influence exerted, for at present she is often able to sleep the night through without resort to the medicine.

Since the success that attended my early efforts with this patient, I have tried these drugs in numerous other cases. I much prefer the action of the antifebrin, which I employ in fifteen-grain doses. In some instances its hypnotic influence seems to be delayed, as in that of paraldehyde, and in such cases I have found it advantageous to have the antifebrin administered two hours before bedtime. I have never seen any bad effects from it when given in this dose and under these conditions. Fifteen-grain doses in fever would, of course, be dangerous, while they are absolutely harmless in the absence of that morbid condition. As there are idiosyncrasies, no doubt, it is best to begin with five-grain doses and creep up to the amount required to produce the desired result.

I have delayed the publication of my paper on this subject because I desired to have numerous cases to report on; but I have decided that it is best to call the attention of my medical brethren to the benefits to be derived from the use of the drug in the manner indicated, and to ask them to add their experiences to my own herein detailed. Very respectfully,

G. DALTON HAY, M.D.

324 EAST FIFTIETH STREET, December 5, 1887.

HOW MR. LAWSON TAIT WORKS.

TO THE EDITOR OF THE MEDICAL RECORD.

TWO ABDOMINAL SECTIONS.

BIRMINGHAM, October 1.

SIR: I send you a report of the following interesting cases, which are historical, and illustrate the character of the work that Mr. Tait is doing.

On September 21st Mr. Lawson Tait was summoned to Italy to operate on the wife of a distinguished American physician, a resident of Rome.

He asked me if I would be "prepared to accompany him in an hour?" After a rapid journey through the most beautiful portion of Switzerland, including the St. Gothard Pass, we arrived at Lugano, a small Italian town nestling among the mountains at the southern extremity of Lake Lugano, a small lake forming part of the boundary line between Switzerland and Italy, and exceeding in beauty the famous Lake Como.

The patient, a most estimable lady, thirty-five years of age, distinguished for her beauty and culture, had been a sufferer for many years. Her history is given in the following extracts from letters, written by her husband, to Mr. Tait:

LETTER I.

HOTEL DU PARC, LUGANO, August 3, 1887.

MR. TAIT: In the early part of last January she was seized with severe hystero-epileptic convulsions, which continued almost daily for six weeks, when they ceased. She remained very weak, and it was not until June that I was able to move as far as here. For one month she seemed to gain, and was able to move round a little, and preparations were made to come on. The day before she was to start she was again taken down worse than ever, the convulsions lasting from three to four hours and followed by wild delirium, and for days no sleep. This continued for eight days; then she began to improve, and I was hopeful of being able to get her on by easy stages; but, alas! ten days since she was worse than ever; the mania that followed was of a suicidal character.

I am satisfied nothing will be of service short of removal of the uterine appendages, as those on the right side have been diseased for the last eleven years. At that time she had an abortion, followed by salpingitis, which confined her to her bed for three months. Since then she has had eight abortions at about the second month.

During this attack there has been great tumefaction over the right ovary and tube, with fever and uterine pain. Four days since, a considerable quantity of fetid, greenish-yellow pus escaped from the uterus, in my opinion from the tube; since then she has been much relieved, and there is less tumefaction. I cannot operate on my own wife, and I prefer that you should do the operation; hence I write to ask you when I had better bring her, and whether you prefer to have her stay at your hospital, or where?

P.S.—Two years since she had a similar attack, which lasted four months.

LETTER II.

I am satisfied that my poor wife would not have the strength to travel to London, even by easy stages, and that it will be necessary for you to come here. At the request of the family I have consented to a consultation with Professor Porro, for Tuesday, who undoubtedly will confirm my diagnosis, and even if he does not, my opinion will be the same, and I shall insist on the case being placed in your hands. If he does, my hands will be strengthened, and they will have no chance to charge me with having an operation performed unnecessarily. God knows if there ever was a case calling for interference this is one. I will write or telegraph you immediately after seeing Porro, and will have him write his diagnosis and advice over his own signature.

LETTER III.

August 17, 1883.

Porro commenced his operation yesterday at eleven, and finished by abandoning the operation at a quarter past twelve. He made an incision three and one quarter inches long; he says both ovaries and tubes were so firmly adherent that it was impossible to separate them from the mass of organized tissue in which they were embedded, the slighter adhesions he broke up, and then crushed the base of the ovaries with strong forceps, with the hope, he says, of partly destroying their function. He wished me to feel the attachments, but I declined, as I preferred to leave all responsibility with him. She suffers dreadfully. I give her as much morphia subcutaneously as I dare, but there seems no possibility of controlling it entirely. There is continued nausea and vomiting. Pulse very weak and compressible, 80; temperature, 99°.

REPLY TO NO. III.

7 Crescent, Birmingham, August 20, 1887.

Dear Dr. ——: I am greatly distressed by the information conveyed in your letter of this morning, the more so as it is exactly what I feared would take place. The opprobrium of this particular kind of work will in future be the incompleted operations. My experience, now extending over a long series of years, satisfies me that there is no case in which adhesions of the uterine appendages are such that it is impossible to remove them by skilled and experienced fingers. I grow more and more satisfied that nobody ought to meddle with these cases except those who have, or are likely to have, an extended experience with them. It is a great pity that Professor Porro left the operation unfinished. If your wife survives it, let her rest for two or three weeks, and either let me go over to Lugano and operate, or bring her here. I will undertake that the operation shall be finished.

Yours very truly,

Lawson Tait.

LETTER IV.

August 30, 1887.

The principal pain now is from the cystitis, which is very distressing. I am having the bladder washed out with solution of boric acid, and giving her lithia water. I shall run over to London the first week in September, and shall come down to Birmingham to confer with you, when I can give you more particulars than by note.

I notice in the *Gynecological Journal* for August your report of the case first operated on by Dr. Jos. Williams, and afterward successfully by yourself, and showed it to my wife for her encouragement.

Mr. Tait examined the patient and expressed himself as much relieved, as the operation would be less serious than he had anticipated, and to me he expressed the opinion that he would have the offending organs "out in less than three minutes." The operation was appointed for the following day at eleven A.M. Dr. Porro was telegraphed the time of the operation, and requested to be present. A reply was received stating that he was out of town, and that the notice would be forwarded to him.

On the morning of September 24th, after the administration of an anæsthetic by the local attending physician, Mr. Tait performed the following operation:

The abdominal cavity was opened through the lower third of the old cicatrix, two fingers passed within, and with marvellous dexterity the appendages were separated from their adhesions at the bottom of Douglas' cul-de-sac, brought up within the abdominal wound and tied off. The appendages of the right side were treated in the same way, a small drainage-tube inserted, and the abdominal wound closed with silk-sutures, the whole operation being completed inside of five minutes. The husband, who stood at Mr. Tait's left, expressed himself as amazed and delighted beyond measure.

The patient made an easy recovery, the temperature remained almost normal, and at the time of our departure, three days after the operation, the friends stated that she was in better health and spirits than she had been for years.

The specimens showed no signs of the crushing to which they had previously been subjected, but presented much the same appearance as hundreds of other specimens which Mr. Tait had removed. The fimbriated extremities of the tubes were agglutinated to the ovaries, and both covered with bands of newly formed fibrous tissue, showing the characteristics of an old salpingitis attended with repeated attacks of pelvic peritonitis.

The remainder of the day we spent fishing on the lake, within easy call, should any necessity require. The following two days were occupied in an excursion over Lakes Lugano and Como, as far as Milan, and included a visit to Dr. Porro, and other prominent points of interest in Milan.

The Ospitale Maggiore, at Milan, is a large, rectangular structure of brick, with nine open courts in the centre. It is antiquated in appearance, as most of the building was constructed in the fifteenth century. Here Dr. Porro has at his disposal several hundred beds, mostly devoted to obstetrical cases. On our arrival Dr. Porro had already made his visit to the wards, but he kindly showed us around, pointing out many striking and interesting cases. Dr. Porro stated that he performed a great many abdominal sections during the course of the year, but I am unable to give you any information as regards the number or the results.

The odor of iodoform and carbolic acid pervaded all the wards, and it was stated that thorough antiseptic precautions were observed in all classes of cases.

Judging from the showing of some of the temperature charts, all of the cases do not pursue a perfectly aseptic course.

The news rapidly spread through Lugano that "Il primo professore di tutto il mundo" was in the country, and Mr. Tait was requested to operate upon a case of multiple myoma of the uterus. The patient had been a great sufferer for several years, and was much reduced by continual uterine hemorrhages.

She had consulted a distinguished surgeon of the country, who had refused to operate, and had expressed the opinion that if an operation were attempted the patient would die on the table.

The patient resided in an old stone villa of the thirteenth century, situated in the suburbs of the town. All the floors were of stone, and the room selected for the operation had but one window, not more than two feet by three in size.

After the patient was ætherized Mr. Tait made an incision five inches in length; this was afterward somewhat enlarged. Inserting his corkscrew, he rapidly delivered through the abdominal opening the tumor, consisting of three nodular masses, each the size of a child's head, together with a cystic ovary, the seat of a hæmatoma. The base of the tumor was encircled with a temporary clamp and enucleated from its pedicle.

A Koeberle's serre-nœud was applied and the pedicle

fixed in the lower angle of the abdominal wound, which was closed with silk sutures. The stump was treated with perchloride of iron, and a dressing applied. At the close of the operation, which was completed in fifteen minutes, the patient's pulse was full and strong, and beating at the rate of 80 per minute. The patient, although unfavorably situated for such a serious operation, made a very happy recovery. Two hours after the above operation we left Lugano for Birmingham, arriving here just one week from the day of our departure.

I cannot close this hasty sketch without expressing my belief that Mr. Tait is one of the jolliest travelling companions in all England; his information is universal, and what he says is always interesting.

C. N. Dixon Jones, M.D.,
of Brooklyn, N. Y.

WHO USED SUBMUCOUS INJECTIONS FIRST?

To the Editor of The Medical Record.

Sir: I notice in The Medical Record, of October 22, 1887, an article by Dr. W. F. Chappell, of New York, on "Submucous Injections in Chronic Throat and Nasal Disease."

Now, while the author does not seem to claim priority for this procedure, yet he makes no mention of the literature of the subject. I wrote a paper on "Hypodermic Medication in Catarrh" for my thesis for fellowship in the American Laryngological Association, in the spring of 1882. This paper was published in the "Archives of Laryngology," vol. iv., No. 1, January, 1883, and reprinted.

So far as I could judge from the description, the syringe and needles must be almost identical with my own, and the procedure was about the same, although I used ergot instead of carbolic acid.

Yours sincerely,
Thomas Amory de Blois, M.D.

5 Park Square, Boston, October 28, 1887.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 6 to December 10, 1887.

Sternberg, G. M., Major and Surgeon. Assigned to duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md. S. O. 285, A. G. O., December 8, 1887.

Cleary, P. J. A., Major and Surgeon. Assigned to duty at Fort Wingate, N. M. S. O. 285, A. G. O., December 8, 1887.

Anderson, C. L. G., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort McDowell, Ariz. S. O. 285, A. G. O., December 8, 1887.

Taylor, A. W., Captain and Assistant Surgeon. Assigned to duty at Fort Robinson, Neb. S. O. 285, A. G. O., December 8, 1887.

Appel, A. H., Captain and Assistant Surgeon. Assigned to duty at camp at Highwood, Ill., relieving Assistant Surgeon H. O. Perley. S. O. 285, A. G. O., December 8, 1887.

Perley, H. O., Captain and Assistant Surgeon. Will rejoin his proper station (Fort Wayne, Mich.). S. O. 285, A. G. O., December 8, 1887.

Hoff, John Van R., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect on or about the 12th proximo. S. O. 128, Department of the Missouri, November 30, 1887.

Munday, Benjamin, Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect about December 15, 1887. S. O. 280, A. G. O., December 2, 1887.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 10, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	8
Scarlet fever	115	22
Cerebro-spinal meningitis	3	3
Measles	46	0
Diphtheria	187	48
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

The Journal of the Dead Failures.—Mr. Edward Garraway, in the *Edinburgh Medical Journal*, announces his intention of establishing a new medical journal. He says: "The title of my venture would be 'The Dead Failure, Limited.' Ignoring the maxim that 'Dead men tell no tales,' my book would be made up of nothing but dead men's tales. 'The journals of the day teem with the triumphs of medicine and the exploits of surgery. Everybody records his successes and narrates his victories, till at length one begins to wonder how it comes about that anybody ever dies. People, nevertheless, do die, apparently from sheer perversity, or, as our transatlantic brethren might more pertinently put it, from 'pure cussedness.' Certainly, if we believe, it is no more the fault of the medicine men of the present generation than it was in the days of the celebrated Dr. I. Lettsom, who, you may remember, in allusion to his unhappy patients, is said to have written:

'I physics, bleeds, and sweats 'em;
If after that they chance to die,
It's not my fault—I. Lettsom.'

Now 'The Dead Failure, Limited,' is intended to search out 'the reason why.' It will have nothing to do with cures and recoveries. Defeats and disappointments, whether brought about by negligences and ignorances, sins of omission or commission, errors in judgment, or deficiency in tact—no matter from what cause—unsuccessful cases will alone be admitted."

Professor Albrecht, of Vienna, advances the theory that the defects found in the lower extremities of man, such as bow-legs, knock-knee, etc., are the punishment entailed upon him for assuming the erect posture, thus departing from the original scheme of nature which intended him to go upon all-fours. He also looks upon the scrotum as no more than a normal inguinal hernia, and the descent of the testicle into them as a dislocation of an organ from its natural position, owing to the assumption of an unnatural posture.

Dressing for Broken Finger.—At a recent meeting of the Philadelphia County Medical Society, Dr. A. C. W. Beecher reported a case of simple fracture of the distal phalanx of the index-finger, which he treated by applying a narrow bandage from the end of the finger to the second phalangeal joint, making two layers. This he coated thickly with collodion, which, drying and hardening quickly, made a neat, smooth, and stiff waterproof casing, which was worn, with but one change, until the fracture was cured.—*Medical Reporter.*

Ninety Tape-worms and One Girl.—In the *Correspondenzblatt für Schweizer Aerzte*, ~~August 15, 1887~~, p. ~~485~~, Dr. Roux, Surgeon of the Cantonal Hospital in Lausanne, describes a singular case in which the patient, a girl aged twenty-one and a half, discharged (after two six-gramme doses of extract of male fern) at least ninety bothriocephali lati. The worms passed out in a bundle, the

patient assisting the delivery by tearing the package with both her hands, and at the same time uttering shrieks like a woman in labor. The agonizing delivery lasted ten minutes. The mass of parasites filled up half of a chamber utensil. The disentangling and counting took exactly four hours and a half of the author's time. As an individual only such a worm was considered which had a head, and at its other end measured not less than 3 or 4 millimetres in breadth, or which had an absolutely thread like (though headless) anterior end, and measured not less than one metre in length. Numerous very long ribbons, which did not answer those conditions, were left out of the reckoning; neither were any of the ribbons which had been discharged several times by the girl for a couple of weeks previously taken into account. There could be no doubt, therefore, that the number of worms, given as ninety, in reality far surpassed that figure. The length of individual bothriocephali varied between 250 and 60 centimetres, a large number measuring only between 100 and 60. Except some slight nervous phenomena (such as occasional headaches, vivid dreams, *semi-somnambulism*), the patient did not present any morbid symptoms. She was a robust and ruddy, and even cheerful and active, country girl, with excellent appetite and digestion, and with ninety-five or ninety-seven per cent. of hæmoglobin in her blood (as Gowers-Sahli's hæmoglobinometer showed). The case seems to give a support to Dr. Zschokke's theory, according to which the prevalence of bothriocephalus latus among the population residing around Lake Leman should be attributed to the eating of infected fish, mainly that of perch (*perchette*). At least the girl, who had come to the locality from Argovia about the Easter of 1884, during a period of several months' duration, in 1886, was dining on perch (and bothriocephali) once a week, or even still more often, the patient residing at the time at Bonvard, near the lake mentioned.—*Brit. Med. Journ.*

Normal Delivery as Practised in Vienna.—The successive steps at delivery of a child in Vienna are said to be as follows: Cleanse the rectum. Support the perineum. Do not allow the fingers to touch any part of the vagina if it is possible to avoid it. After birth, put the child on its right side to give its heart the best chance. Do not tie the cord until it stops pulsating. Give the child a full bath. The joints of the child, particularly, are rubbed with oil or lard. A small injection is thrown into the rectum to see if the parts are normal. A solution of nitrate of silver is dropped into the eyes. The child is then dressed.

The Late Professor von Langenbeck began his day's work with a class in operative surgery, which was held from 6 A.M. to 8 A.M. The remainder of the morning was devoted to consultations and operations in private. He was due at his clinic at 2 P.M., but arrived half an hour before that time for the purpose of receiving in his private room the visits of private friends, military surgeons, medical men with special introductions, and arranging with his assistants (at this time Drs. Busch, Trendelenburg, and Bose) the order in which the various cases sent to him should be brought forward in the clinic. At two o'clock precisely he entered the theatre, wearing a specially made, tightly fitting coat of black material (scrupulously cleaned for each day); here he examined students most carefully, demonstrated the cases, and performed any necessary operation. We know of no other hospital in Europe where richer pathological and operative material was at the disposal of anyone single surgeon than that over which the late von Langenbeck then presided. He was fluent of speech, possessed of sympathetic voice, great charm and impressiveness of manner, with a most intimate knowledge of every detail of his subject, and produced an effect upon his hearers which no pen can adequately describe. As an operator he was in the very first rank, original, bold without recklessness, and of great anatomical knowledge. Of endless zeal and untiring industry, Langenbeck combined in himself all the elements which go to make a good surgeon and teacher, and there are few men who have left a deeper impress on the surgery of their time, not merely by reason of his own individual work, but indirectly through those who were his pupils, and are now so worthily occupying leading positions in the universities throughout Germany. An aristocrat in appearance, manner, and feeling, modest in demeanor, the trusted friend and councillor of his sovereign, revered and esteemed by all classes of society, the friend of all and enemy of none, his country will long mourn a loss which will also be felt throughout the empire of surgery.—*The Lancet.*

The Southern Surgical and Gynecological Association.—A meeting for the permanent organization of the Southern Surgical and Gynecological Association was held in Birmingham, Ala., on October 12th, in response to many urgent requests of physicians in the South that the Alabama Association would extend its membership so as to include all the Southern States. Membership was extended to the members of the Alabama Surgical and Gynecological Association, and to those who had responded favorably to the Secretary. The Association includes all the Southern States, and its meetings will be held on the second Tuesday of September of each year at such places as may be selected by the Association. Dr. W. D. Haggard, of Nashville, Tenn., was elected President; Drs. R. D. Webb and J. W. Sears, of Birmingham, Ala., Vice-Presidents; Dr. W. E. B. Davis, of Birmingham, Ala., Secretary; and Dr. H. P. Cochrane, of Birmingham, Ala., Treasurer.

Sources of Syphilis in the Female.—Professor Fournier, the French syphilographer, has compiled some statistics relating to the sources of syphilis in the woman. During twenty-seven years he has made notes, in his private practice, of 887 cases, of which 842 were of sexual, and 45 of non-sexual, origin. In the second group, which constitutes a series of cases deserving, according to him, the qualification of "unmerited syphilis" ("the syphilis of innocents"), there were 7 cases in which the disease was inherited; 4 in which the disease was accidentally contracted in infancy; 8 cases of infection transmitted to wet-nurses by infants hereditarily tainted; 5 cases of midwives who had contracted syphilis in their fingers or hands in the practice of their profession; 12 cases of "domestic contagion," derived from nursing infants belonging to nurses or servant-girls that were syphilitic (these twelve cases were all observed in married women or young girls); 2 cases of syphilis transmitted by vaccine; 2 cases of syphilis communicated by catheterization of the Eustachian tube; 1 case consecutive to rape; and 4 of unknown derivation, but certainly not of venereal origin. Of the 842 cases in which the disease was clearly of sexual origin, 366 were women of known dissolute habits—"women of the town;" 220 were married women; and 256 were persons whose social condition remained unknown. Passing by the first group, that of the abandoned women, 65 of whom (17.7 per cent.) were play-girls (*filles du théâtre*), and analyzing the 220 cases of syphilis in married women, it appeared that of these there were 164 "that had been honestly and conjugally infected with syphilis;" that is, these women had contracted the disease from their husbands, and without any fault of their own. Of the 220 married women, 56 were doubtful cases; these latter had contracted syphilis from "lovers," for their husbands, when examined, were found exempt from syphilis; a few of them had been syphilitic before their marriage.—*Boston Medical and Surgical Journal.*

The Influence of Mustard and Pepper on Digestion and Metabolism.—Dr. P. Burjinsky gives the following as the results of an experimental inquiry into the effects of mustard and pepper: 1. When given with meals in small quantities, in the daily amount varying from 8 to 18 grammes of the condiment prepared of 50

grammes of the mustard-flour and 80 grammes of warm water—that is, when taken exactly as in daily life—mustard does not show any influence on the assimilation of nitrogen of mixed diet (consisting of butcher's meat, milk, white and rye bread, potatoes and beef-tea, and tea). 2. Pepper, in the daily quantity from 0.7 to 1.0 gramme, lowers the assimilation, the decrease varying from 0.4 to 2.3 per cent. 3. Mustard, in the daily amount of 4 to 10 grammes, lowers the assimilation of fats, the fall amounting to 2.2 per cent. 4. Neither mustard nor pepper shows any influence on the systemic metabolism. 5. Mustard somewhat improves appetite, while pepper diminishes it. 6. Mustard has no influence on the daily quantity of urine, though Dr. Lauder Brunton, in his classical "Text-book of Pharmacology," 1885, p. 379, regards the condiment as a diuretic. 7. But pepper, as a rule, increases the secretion of urine, the daily surplus varying from 3 to 14.8 per cent. The urine at the same time acquires a strongly pronounced characteristic odor. Probably both the diuresis and odor should be attributed to the presence of an essential oil isomeric with turpentine (Flückiger). 8. Both mustard and pepper very frequently give rise to gastro-intestinal disturbances—colics, diarrhœa with eight to ten stools a day—in persons unaccustomed to the use of the condiments in question.

Cyanide of Zinc is said to produce valuable results in cardiac cases, more particularly in cardiac neuroses, in which it is stated to act quickly and certainly. Pain in the region of the heart, palpitation, and want of rhythm are quickly relieved, and in some cases cured. It is given in doses of one-tenth to one-eighth of a grain three times a day.

Diseases which Reduce the Alkalinity of the Blood.—From a painstaking inquiry touching this subject, Professor v. Jaksch has arrived at the following conclusions: 1. Fever reduces, in greater or less degree, the alkalinity of the blood. 2. A lessened alkalinity is always observed in uræmia. 3. Hepatic affections involving the parenchyma of the liver lessen the alkalinity of the blood. 4. Leukæmia, pernicious anæmia, and chlorosis diminish the alkalinity of the blood. 5. The same thing occurs in poisoning with carbon dioxide.—*Zeitschrift für Klinische Medicin.*

To Stimulate Medical Research.—Beyond question the ultimate object of all medical investigation is to enable us to combat disease. The agencies used for this purpose and the methods of employing them are treated of under the title of Materia Medica and Therapeutics. To this branch of medicine all other branches are tributary; through it they all reach their object, without it they all fall short of a practical result. It is therefore the one branch which cannot be neglected if medicine is to be anything more than barren theory. It was this conviction which led to the formation of a Section on Materia Medica and Therapeutics in the Academy of Medicine. The object of this circular is to call the attention of the profession to this Section and to invite their hearty co-operation in its work. It is believed that much can be accomplished by methods somewhat different from those usual in medical societies. While the reading and discussion of papers is most useful, the addition of collective observations on the effects of remedies or methods of treatment will, it is thought, advance still more our knowledge of therapeutical resources. It is proposed to appoint committees to take up different remedies, find out all that is known about them, subject them to repeated practical tests, and report upon them to the Section, these reports then being made the subjects of discussion. These reports will be published, so that each worker will have full credit for what he does. Periodical reports on the progress of therapeutics will also be made. This work opens a field especially to the younger and more ambitious members of the profession, who are urged to come forward and take an active part. A man's best work is usually the product of the enthusiasm of early professional life, which is too often lost while waiting for older men to take the lead. Fellows of the Academy desiring to join the Section are invited to send their names to the Secretary. *Co-operation is also solicited from those not Fellows.*—Andrew H. Smith, M.D., Chairman.

The Late Dr. Theodore Romeyn Varick.—At a largely attended meeting (the largest ever held in the county) of the profession of Hudson County, held in Jersey City, N. J., on Saturday morning, November 26, 1887, the following preamble and resolutions, presented by the committee, consisting of Drs. Gordon, Kopetchny, and Morris, were unanimously adopted:

The hand of death having removed from among us our esteemed associate Theodore Romeyn Varick, whose long and distinguished service, as physician and surgeon, render it eminently proper that we should place upon record our appreciation of his merits; therefore, be it

Resolved, That in his close identification with a specific aim (the advancement of the art of surgery), his devotion to the profession, his self-reliance and unswerving principle, striving for the right as best he understood it, he has nobly fulfilled his mission, and in his death the profession has lost one of its ablest exponents, the people a great friend, and the State an estimable citizen.

Resolved, That we tender to his afflicted family our earnest sympathy in this their hour of trial.

Resolved, That we attend the funeral services, from his late home, in a body, and that a copy of these resolutions, signed by the President and attested by the Secretary, be transmitted to the family of deceased, and published in the city papers, and The Medical Record and *New York Medical Journal.*

A. A. Lutkins, M.D., *President.*
Wm. Perry Watson, *Secretary.*

The following are the resolutions of the Medical Board of St. Francis' Hospital regarding the death of the late Dr. T. R. Varick:

The Sisters in charge and the Medical Staff of St. Francis' Hospital, Jersey City, deploring the sudden and unexpected death of their late distinguished associate Dr. Theodore Romeyn Varick, unite in giving public expression to their great sorrow, and desire to place on record their appreciation of the exalted character, superior abilities, and valuable services to the science of medicine of their late friend and colleague.

Resolved, That words are inadequate to express our sense of bereavement in the loss of one who pre-eminently excelled in all the attributes of a great and true physician—his erudition of mind, clear and logical; his many and valuable contributions to medical science, particularly in the branch of surgery, original, concise, and practical; his noble devotion to his profession, and the tireless industry exemplified in the daily practice of his art; his purity, simplicity, and sterling honesty of character—open and frank himself, he hated sham and deceit; his courtesy and ethical conduct toward his professional brethren. Endowed with all the virtues that add lustre to the character of a Christian gentleman, he was loved, revered, and admired by his friends. That the great heart, actuated by the highest aims and noblest impulses for the betterment of suffering humanity, and so full of love and generosity for his friends, is stilled in death, is a grief to us that time is powerless to assuage.

Resolved, That we tender to the family of the deceased our deep sympathy in this great affliction that has come upon them. Words, indeed, we know, are idle to comfort anguish of heart such as theirs, and we can but sorrow with them.

Resolved, That a copy of these resolutions be sent to the family of the deceased, and be published in the Jersey City daily papers, The Medical Record, and the *New York Medical Journal.*

Original Articles.

INTRAPERITONEAL RUPTURE OF THE URINARY BLADDER—LAPAROTOMY, WITH UNSUCCESSFUL RESULT.

By E. L. KEYES, M.D.,

NEW YORK.

I RECORD the following case of unsuccessful laparotomy for intraperitoneal rupture of the bladder for its statistical interest in connection with the brilliant new departure in the treatment of this grave condition, instituted by Sir William MacCormac, whose success in two consecutive instances was given to the world through the *London Lancet*, December 11, 1886.

My further intent is to indorse the method on account of the facility of its execution and its manifest appropriateness.

P. K——, twenty-two years of age, the driver of an ash-cart, while in a state of extreme intoxication, was run over by his own cart at 5.20 P M., December 1, 1887, and immediately brought to Bellevue Hospital, where he was examined at 6 P.M. by Dr. T. McCann, house-surgeon in charge of the third surgical division.

The patient was violently drunk and unable to give any account of himself or his injuries. He had a large scalp-wound which nearly separated his ear, and a lacerated wound of the scrotum, but bore no evidences of other injury, and complained of nothing except the restraint in which he found himself.

Temperature, 99° F.; pulse full and bounding; no complaint of pain upon manipulating the abdomen. His wounds were attended to and no suspicion of injury to the bladder was at first entertained. He urinated at 1 A.M., December 2d, the quantity and color of the fluid not being noted.

At 8 A.M., no urine being passed, the abdomen was percussed by Dr. McCann, and found to be slightly tympanitic and without any line of bladder-dulness. Pain was complained of in the region of the liver. The temperature was still 99°. The legs were slightly drawn. The patient vomited a greenish fluid. A catheter was passed, and drew off half an ounce of bloody urine.

At 9.20 A.M. Dr. Dennis saw the patient, passed a catheter, and obtained nothing. He then injected ℥ viij. of Thiersch's solution and drew off ℥ xvj. (Weir's method), exactly double the amount injected. The fluid was moderately bloody. Dr. Bryant also saw the patient, as did Dr. S. Alexander; all concurred in suspecting intraperitoneal rupture of the bladder. Morphine was continued, and the question of operation discussed. At 1 P.M. temperature had fallen to 97½°. Dr. Dennis ordered a large injection of Thiersch's solution. Forty ounces were thrown in. The bladder did not bulge above the pubis, and only ℥ xx. could be drawn off. Vomiting became continuous and collapse imminent. I did not hear of the case until 4 P.M., but immediately decided to operate as the only chance, regretting that I had not received news of the matter earlier. Dr. Dennis kindly consented to join me in the operation, and the patient was etherized immediately after 4 P.M., twenty-two and a half hours after the receipt of the injury. One of MacCormac's operations was performed twenty four, the other twenty-seven hours after the receipt of the injury. Dr. Stephen Smith and Dr. S. Alexander, with Dr. McCann and the house staff, also assisted at the operation.

The tense abdomen was promptly opened in the median line. When the peritoneum was incised there issued a gush of bloody fluid. The intestines were found to be somewhat congested and freely coated with patches of coagulated lymph. The rent in the bladder was brought at once into view. It commenced centrally above, just in front of the peritoneal reflection, and extended a full inch and a half, as a clean cut, directly backward in the median line, involving the peritoneum and all the coats of the bladder as sharply as if the cut had been made with a knife.

Nine silk sutures were placed after the Lambert method, not puncturing the mucous coat of the bladder. The facility with which these sutures were introduced by the aid of a curved Reverdin needle was surprising. The topmost and lowest sutures were placed well away from the corresponding angles of the wound, and when all had been tied the incision was a continuous line of inverted peritoneum, as clean and straight as possible. The bladder was now twice distended with warm Thiersch's solution, and the sutured wound proved to be perfectly water-tight.

No injury of the liver or intestines could be detected. The peritoneal cavity was freely irrigated, a large glass drainage-tube introduced into the bottom of the recto-vesical cul-de-sac, and the abdominal incision closed with silk, drained, and antiseptically dressed. A catheter was tied in the bladder through the urethra. About an hour and a quarter, all told, was consumed in the operation. Hemorrhage was trifling.

The patient was put to bed with hot bottles, and every effort made to rally and sustain him. At 6.30 P.M. the temperature reached 102⅘°; pulse, 134. Both kept on increasing steadily, the vomiting continued unabated, and the patient was wildly violent through the night, spending his time in cursing his nurses. Small quantities of slightly tinged serum were removed by suction from the glass drainage-tube from time to time, and eight ounces of clear urine passed by the catheter before death, which occurred with a temperature of 107°—pulse, 162—at 11.40 A.M., December 3d, about eighteen hours after the operation.

Autopsy.—The abdomen only was examined after death. The peritoneal cavity contained perhaps an ounce of serum tinged with blood. The sutured wound in the bladder was found exactly as it had been left. There had been little or no attempt at repair, if exudation of lymph is to be considered the sign of the reparative process. The bladder was injected through the urethra and bore distention well; only when it rose up and became very tense a small, sudden spirt of a fine stream of water appeared about centrally between the sutures. This was produced by the tension within the bladder, a tension impossible during life with the catheter tied in. No leakage of urine had occurred, and the suturing had evidently been effective. There were no other intra-abdominal lesions. The brain was not examined.

Remarks are unnecessary. I desire only to repeat that the operation is very easy to perform with the aid of the Reverdin needle, and that the sutures placed by its aid were effective in closing the bladder water-tight and preventing leakage.

The patient was a drunkard of the lowest order. He never rallied from his drunkenness, and doubtless would

have failed as promptly had he been operated on earlier in the day. In Holmes'[1] successful operation only six hours intervened between the injury and the use of the knife, yet in both of MacCormac's cases more than twenty-four hours had elapsed. In Mr. Walsham's[2] successful case about twelve hours had elapsed.

Instances like that of Henry Morris,[3] in which an autopsy of a case of intraperitoneal vesical rupture showed the lesion to have been the giving way of an old cicatrix —that cicatrix having followed an intraperitoneal vesical rupture, treated successfully by tying in the bladder a gum-elastic catheter, at the Middlesex Hospital in 1879— and the other recent case recorded by Drs. Benham and Greig Smith,[4] in the *Glasgow Medical Journal*, where an imbecile pushed an umbrella whalebone up his urethra into his bladder, and, dying two years later of Bright's disease, the whalebone was found partly within the bladder encrusted with phosphates, partly in the peritoneal cavity, are plainly exceptions, and intra-peritoneal bladder wounds must still be considered mortal. For the patient whose history is narrated above the choice was between inaction and laparotomy, and I consider the operative attempt to have been justifiable, although unsuccessful.

1 Park Avenue, December 14, 1887.

FRACTURE AND DISLOCATION OF THE SPINE.[5]

By ISAAC W. CHISHOLM, M.D.,

New Concord, O.

Fortunately, fractures and dislocations of the spine are accidents of rare occurrence, for in a large majority of cases they prove fatal. Owing to the limited motion of the vertebræ, through their being so firmly bound by strong ligaments and powerful muscles, it is natural to infer that a dislocation of these bones would be of rare occurrence, and it has even been wholly denied by some surgeons, yet from recorded cases it has been clearly proved that these accidents may and do occur—the causes producing both dislocation and fracture being so closely allied that they may be said to be identical; in fact, they may all be summed up in two words—extreme violence.

The following are the generally accepted symptoms of dislocation and fracture of the different parts of the vertebral column :

If fracture or dislocation occur above the origin of the phrenic nerve, so that pressure is made upon the spinal cord, there is a disturbance of respiration, and death usually closes the scene.

In fracture of the dorsal vertebræ, unless very high up, the upper extremities will be free from paralysis; in either case the bowels will be stricken with torpor, being unable to expel their contents, and the patient's distress will be greatly increased by the accumulation of phosphatic matter in the urine, causing chronic inflammation of the bladder.

Fracture and dislocation of the lumbar vertebræ cause, in the lower extremities generally, a cessation of volition and sensibility, varying, no doubt, with the direction in which the vertebræ may be thrown, whether forward or backward; and authors generally state that the fæces pass involuntarily, although I think I am justified in saying, from the following case, that the very opposite (extreme torpor) may happen—yet it may be an exceptional case, for in surgery we sometimes have to be governed by exceptions, or anomalous cases.

In the aggregate, I think we are safe in stating that if fracture or dislocation of the vertebral column occur above the origin of the phrenic nerve, thus causing pressure upon the spinal cord, immediate death will result; whereas, if the injury be inflicted in the lower portion of the dorsal, or along the line of the lumbar vertebræ, it will cause paralysis of the lower extremities, accompanied by incontinence and constipation, as well as involuntary discharges from the bowels.

The prognosis of both fracture and dislocation of any part of the spinal column should be looked upon with grave apprehension. "Few persons," says the distinguished American surgeon, Professor Gross, "ever recover."

As to the treatment of that class of injuries now under consideration, nothing would be more difficult, perhaps, than to lay down a methodical procedure; so difficult would it be, that he who should attempt it would in all probability arrive at the conclusion that it was one of the grandest failures he ever made.

In no case, perhaps, can nature assert her superiority over those of us who may be called in to play the part of physician, surgeon, or both, than in the treatment of injuries of the spine. In my opinion, Professor Gross never spoke a greater truth than when he said, "Time and a masterly inactivity will accomplish more than all the interference of the best surgeons, except that when the symptoms are well marked, and there is danger of the patient perishing, an attempt, however desperate, would be perfectly justifiable and proper; for," he says, "if we succeed, we obtain a victory; if we fail, we cannot but hasten an occurrence otherwise inevitable."

The greatest danger to be encountered, no doubt, in the majority of cases, is the too frequent annoyances of the meddlesome surgeon, even to the oft-repeated taking of the temperature, feeling of the pulse, counting the respiration, waking the patient for the administration of either food or medicine, repeated inquiries as to their condition, all of which tend to harass the sufferers and add to their already over-excited nervous system. I was called to attend the following case, and made a report of it to the Cincinnati *Lancet and Clinic*, one year after the accident, September 27, 1879.

Charles G. G——, aged ten, residence New Concord, O., attended a soldiers' reunion in the city of Zanesville, O., September 19, 1878, and while seated under the speakers' stand the structure gave way, the timbers striking him in such a manner as to throw his head violently forward and downward between his legs. When extricated, his eyeballs were protruding from their sockets, and his face congested to a purplish hue, presenting altogether a ghastly appearance.

On being taken to the house of a friend, Drs. Oatley and Culbertson were called, and, in consultation with other distinguished surgeons of Zanesville, they found, upon examination, a dislocation and fracture of the third lumbar vertebra, it being thrown backward. Erichsen says he knows of no case where the lumbar vertebræ have been dislocated unless attended with fracture; and in accordance with such high authority I think we are justified in stating that it was so in this case, although a positive diagnosis was impossible. Some, however, take the position, I believe, that the force required to produce dislocation of this character is so great that it would be impossible for a dislocation to occur without also being attended with fracture, and in this case the fracture occurred, we think, in the body of the vertebra, as shown in the cut.

On October 2d he was brought to his home (New Concord, O.), two weeks after receiving the injury, and placed in my charge, Dr. Oatley accompanying him, and informing me of the great difficulty of obtaining a passage from the bowels. We concluded to try croton oil suspended in castor oil, and injections of soapsuds and turpentine, but these had little effect. After frequent administration of the oils I abandoned the course, as it sickened him, causing violent vomiting, which was attended, however, with some beneficial results, as the act of vomiting caused small portions of fecal matter to be

[5] Read before the Zanesville Academy of Medicine, and published by request.

thrown down into the rectum, whence I could remove them with my finger. I concluded to use injections and my finger, getting away all I could in this manner, and abandoning all physic.

About every ten days he would be attacked with nausea and vomiting, the pulse would become greatly accelerated, and the temperature would rise to 105° F. I concluded to try the experiment of feeding him entirely on "slops" or fluids, but this not having the desired effect I gave orders to administer *no food whatever* at those periods, and applied mustard and hops to the bowels, as they became at those times extremely tender and *sensitive* to the touch. As there was retention and incontinence of urine I gave him for a while fluid extract of buchu, citrate of potash, and sweet spirits of nitre to assist the function of the kidneys, hoping also to effect a reduction of the temperature. To my great satisfaction the irritability of the stomach, together with all the other untoward symptoms, were cut short, the tongue commenced to become clean, and he began to have a moderate desire for food. I noticed that previous to one of these attacks the tongue would become coated, his desire for food would begin to lessen, and there would be an increase of albumen and urea in the urine. I would immediately order no food to be given, and apply the mustard and hops to the bowels (abandoning all medicines that I had been administering for the purpose of assisting the function of the kidneys and reduction of the temperature), relying solely and wholly upon the total abstinence from food of any kind, and allowing him to drink all the water he desired, which seemed to accomplish the purpose which I intended, most admirably.

Some time in January following he was seized with violent spasmodic contractions of the limbs, so that they would be almost drawn to his chest, and at times the muscles of the face, arms, and neck, would be affected, causing him to be tossed about involuntarily. At one of those periods his breathing became involved, causing him to utter at times, "I can't get my breath;" but, fortunately, this was the only time in which respiration became implicated.

I applied a plaster-of-Paris jacket about three months after the injury, but was compelled to remove it on account of one of those "sick spells" coming on, necessitating the local application of the mustard and hops. For the nervous twitchings (herein mentioned) I gave the "bromides" singly and combined, and sometimes in addition with tincture of valerian, but obtained better results from the administration of tincture of valerian alone. He seemed to suffer greatly for the first two or three months, when he would moan in the most pitiful manner. For this I gave him McMunn's elixir of opium at regular intervals and with good effect.

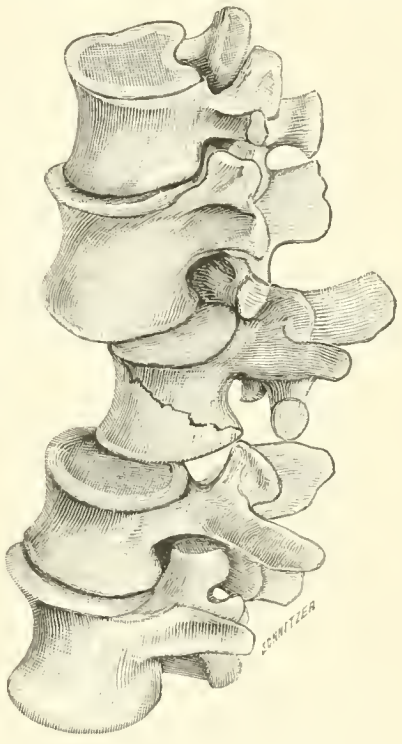
The whole time I had to use the catheter to draw off the urine, and also means to empty the rectum. This was continued for six months, when nature was so restored that all artificial means were abandoned.

As soon as the weather would permit, I placed him a chair, and with his head uncovered took him out of doors, and placed him in such a position that the sun shone directly on him, and I noticed, after a few days, the red tint returning to his pale and wan cheeks. When the weather became inclement, as it frequently is in the early spring, he had to remain in his room. The red hue vanished from his cheeks and he became as pale as ever; but on the return of fair weather I repeated the *sun-bath*, when the red tint or healthy tinge could again be seen returning.

His toes were contracted, and I had made for him a pair of shoes with very stiff soles, with lacing to the points of the toes. By main force I straightened his toes, and by lacing the shoes tightly upon them I was enabled to retain them in their proper position. I then commenced standing him against the wall, and by supporting him well under the arms he was enabled to take a few steps, until finally, after several weeks, he was enabled to walk across the room by supporting himself with the table and other articles of furniture in the room. From this on he improved rapidly, being enabled to go around, with the assistance of crutches, in a couple of months, and one year afterward was enabled to take part in the sports of his playmates (of course in a limited degree). He was entirely devoid of sensation over the hips and posterior portion of the limbs and feet, except over the internal malleolus and the internal cuneiform bone of the left foot.

When he received the injury there was some lateral dislocation of the verterbræ besides dislocation backward. Nature seemed to have made a reduction of the lateral dislocation, as there was no attempt made to reduce it, and the vertebræ now presents the appearance (as shown in the cut) of a dislocation backward only.

He is now (nine years after receiving the injury) is able to act in the capacity of "salesman" in his brother's con-



fectionery, and is enabled to go around without any artificial support whatever, except that, when he walks long distances, he resorts to the use of his crutches.

The urinary and bowel difficulties have passed away, and sensation is gradually returning to hips, limbs, and feet, and my opinion has always been that, as he grew, the vertebræ would expand or grow, and that when he arrived at adult life sensation would be completely restored; but time only will be able to verify this prediction. He has grown and developed as well as other boys, and I see no reason why my prognosis may not be verified.

October 31, 1887.

To Disguise the Taste of Quinine, Engel recommends a mixture of one part of chloride of ammonium and four parts of extract of licorice to each part of quinine. The ammonia and licorice are to be thoroughly mixed, and kept in powder, to be dissolved in water at the time of administration of the quinine.

Sea-Water and Scarlatina.—A surgeon in England is riding the hobby of sea-water to such an extent that he has actually applied to the authorities to have pipes laid from the sea-board to London, in order to give every child a sea-bath daily. By this means he proposes to stamp out the epidemic of scarlet fever in that city.

THERAPEUTIC MEMORANDA ON DIPHTHERIA, WITH SPECIAL REFERENCE TO THE VALUE OF LARGE DOSES OF OIL OF TURPENTINE.

By SIMON BARUCH, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK JUVENILE ASYLUM AND MANHATTAN HOSPITAL.

To appear before a medical society with a paper on the treatment of diphtheria requires a certain degree of temerity. But yet I hope to demonstrate that I have not called upon you in vain to discuss this old, yet ever fresh, theme. A statement of therapeutical results, obtained from careful observations of a disease which so frequently is the subject of anxious deliberation, may enlist your interest and lead to a free discussion of its merits.

In the consideration of this subject we are met by the same conflicting views which are encountered in the treatment of all maladies, that baffle the best directed efforts at times. The skeptic stands arrayed against the expectant, the conservative against the sanguine, therapeutist. Collective clinical observations alone will, as you, Mr. Chairman, have ably set forth in your recent circular, decide these questions.

As I am uncompromisingly opposed to the plan of idly watching this fell destroyer, or meeting him with a half-hearted resistance, I desire to say a few words on this point.

Henoch, who has lent his great name to a pessimistic view of the value of treatment in diphtheria, said, in a paper before the Berlin Medical Society, in 1882: "I cannot omit the remark that, as reasonable as it may be to seek for remedies against this terrible disease, the perseverance in the search is something surprising. It seems to be believed that it will yet lead to the desired object. But if we reflect that in many other infectious diseases, as scarlatina, measles, typhus, etc., the search for a specific has long ago been abandoned, and that we stand more resigned in the presence of these diseases, the hope of finding a specific remedy against diphtheria must be decidedly weakened."

Whether we shall follow the advice of this learned physician, or not, must be determined by the results of his practice. These are woful indeed! In No. 46 of the *Berliner klin. Wochenschrift*, 1884, Henoch relates 319 cases of diphtheria, which he treated in his clinic, with 208 deaths. Of 111 cases under three years he lost 94! His treatment consisted of irrigation with, and subcutaneous use of, corrosive sublimate, and the administration of arsenic with iron, and papayotin locally for the bad cases. "All these," he says, "failed him."

Henoch misinterprets the present stand-point of therapeutics in infectious diseases. The modern physician does not stand resigned in the presence of these diseases. It is true that he no longer seeks for specifics to cure them; but he adopts such therapeutic measures as are rationally indicated to diminish the dangers of the disease and to ameliorate the sufferings of the patient. Although diphtheria stands in the category of infectious diseases, it is by no means analogous to scarlatina, measles, or typhus. These diseases are self-limited, they have a definite course over a definite period, while diphtheria is a disease of brief duration, destroying life rapidly, and acknowledging no definite rise and fall. We cannot, we must not, fold our hands and await the latter as we may do with impunity in some cases of scarlet and typhoid fever. We must be up and doing, alert and regardful of the indications pointed out to us by the most usual "mode of death." The mildest case of diphtheria may forebode the most serious type, and if there be any therapeutic method, any combination of remedies, by which its duration can be shortened or its type modified, we are obligated to adopt it, no matter what our preconceived views regarding the theory of its origin and course may be.

Clinical results must be our chief, our sole guide.

During the past twenty-five years I have passed through numerous epidemics of diphtheria, occurring in sections of this country widely apart—in the village, on the plantation, in the isolated farm-house, in a large city, among private individuals, in public institutions, among white and colored. Hence my observations have been made under varying climatic and social conditions. In my earlier experience I resorted to the iron and chlorate of potash mixture which is still so much in vogue, sustaining the vital powers by nutriment and stimulants. With these weapons I had coped with numerous cases of diphtheria with almost unvarying success, until I had come to believe that the terrific ravages attributed to this disease were almost incredible. How frequent is this overweening confidence in observations obtained in one's own narrow horizon! How our youthful enthusiasm is nursed and fanned into glowing warmth by a succession of favorable results, until, alas, the day of awakening comes and cruelly arouses us from our dream of security. That the progress of time will relentlessly bring such an awakening, most of us have realized but too keenly. Hence we should approach the discussion of all therapeutic questions with a proper sense of their difficulties, and with a recognition of possible fallacies in our observations.

The day came when, flushed with many victories, I found myself in the presence of a case of diphtheria that baffled me. The system was completely overwhelmed, the cervical and submaxillary glands enormously swollen, throat scarce visible owing to infiltration of palate and uvula, nose blocked; patient died in twenty-four hours. I was too late, thought I, to marshal my forces. Very soon, however, I was undeceived. Other cases occurred, all in an isolated country district, many miles from town and from each other. Perhaps failure was here attributable to insufficient nursing. But I was deprived of this last refuge also when the treatment failed in cases which had been carefully nursed, and which were under my constant supervision. As the years passed experience sobered the judgment, and I began to seek anxiously for new and more effective weapons. The old iron and potash mixture given hourly still continued to bring a large meed of success in mild cases. New remedies sprang up and were vaunted with more or less persistency and clinical demonstration. These were weighed in the balance of reasoning and experience, until, by a process of selection, I have reached a mode of treatment which I desire to submit to your consideration, because it has enabled me to cope successfully with many desperate cases. It is needless to say, however, that I shall continue to strive for improvement.

Before proceeding to analyze the reason for "the faith that is in me," I may refer to my attitude regarding local treatment. I recognize that the local deposit of diphtheria may be either the precursor or the sign-manual of systemic infection. I am more strongly inclined to the latter view, because the weight of clinical evidence is in its favor.

In a disease of so insidious and dangerous a character it is criminal to split hairs. We are in the presence of a formidable enemy, whom we should attack not only in his outworks but in his citadel also, without awaiting the actual onslaught from the latter. It is a well-recognized fact that the diphtheritic deposit rests upon necrotic tissue, and that it is more prone to attack tissue that has been enfeebled by local insult, traumatic or otherwise. We know, for instance, that wounded surfaces, blisters, and the mucous membranes are more prone to its attack than the healthy unbroken skin. On the other hand, we know, too, from post-mortem examinations by Guttmann and others, that when the disease attacks the larynx secondarily, it almost invariably does so by spreading downward from the pharynx. Is it not, therefore, the part of prudence and wisdom, even though we recognize the importance of neutralizing the infectious character of the deposit, to apply all remedies by means which

may not produce a traumatism in its vicinity? Surely this is the dictate of common-sense. And yet there are many who still insist upon cauterizing and swabbing the throat of a struggling child, pointing with satisfaction to the removal of the deposit, while they disregard the sodden bleeding surface left behind as a nidus for a fresh and more extensive deposit; and what is more to be deprecated, they create an admirable surface for systemic absorption. I make it a rule never to apply remedies locally to the throat in patients who are not under absolute control. To be effective these applications should be either strongly caustic, or, if mildly solvent and antiparasitic, they should be very frequently renewed. They would thus involve great fatigue and exhaustion to the patient, which in this disease are to be greatly deprecated.

Disinfection of the throat is best accomplished by the frequent internal administration of tonic, astringent, and antiparasitic remedies; not by the brush, probang, nor atomizer. Neither water nor food should be permitted for ten minutes after the medicine has been swallowed, thus allowing it to bathe the diseased surfaces. When the patient is tractable and willing to aid the attendant, I advise the hourly application of a fifteen per cent. solution of tripsin. In one case a ten per cent. papayotin solution proved equal to tripsin, but much more expensive. In nasal diphtheria the tripsin solution is invariably prescribed, to be applied hourly with the medicine-dropper or soft brush, because this can be accomplished without damaging the mucous membrane even in an intractable child. It softens and pulpifies the false membrane and facilitates its removal by injections of salt water, or 1 to 10,000 bichloride, which in this dangerous form I order applied at frequent intervals. It will appear, therefore, that while I abstain from local treatment in most cases of faucial diphtheria, I apply it vigorously, but gently, by the brush and soft rubber-tipped syringe in all cases of nasal diphtheria. When the air-passages are involved I also resort to local treatment by inhalation of the vapor from boiling lime water impregnated with oil of turpentine—one ounce of the latter to one quart of the former, used continuously. Properly applied these inhalations have aided me in saving several of my patients from tracheotomy. Great care should be taken not to deprive the patient of an ample supply of pure air while the inhaling apparatus is in operation. It is a common practice, which was formerly also pursued by myself, to surround the patient by all possible safeguards against the escape of the medicated vapor. A tent is usually constructed around the couch, excluding to a great extent the air, and compelling the patient to inhale the vapor continuously in its fullest concentration. That this is an irrational practice I became convinced several years ago. A patient suffering from laryngeal stenosis requires a plentiful supply of oxygen. Hence it is of vital importance to enforce at least as free access of fresh air to the chamber in laryngeal as in the other forms of diphtheria. It is only necessary to direct the vapor by means of a tube to the immediate vicinity of the patient's mouth. This application requires constant and unremitting care. In this, as in every other detail in the treatment of diphtheria, vigilance is the price of success; the physician must himself devote time to instructing the nurse again and again. The nurse should be warned against admitting cold-air currents to reach the patient. As the latter is usually more or less somnolent in laryngeal diphtheria, it is not difficult to execute the necessary steps.

The general management of the patient and his surroundings requires no distinct reference in this paper, as it is universally admitted that cleanliness of body, quietude of mind, and gentleness in nursing are among the chief elements of successful treatment. One point, however, I may mention. In severe cases, especially if protracted, a change of rooms produces a marked effect. A fresh room, which has been thoroughly ventilated for twenty-four hours; a fresh bed, supplied with clean, well-aired linen, mattresses, and blankets, and new surroundings, will effect a marvellous change in some protracted cases of diphtheria.

The administration of easily digested broth, milk, and stimulants must be left to the indications of each case. Care should be taken, however, to limit the quantity of food in proportion to the digestive powers of the patient. There exists in this disease, as in typhoid fever, a tendency to overfeeding. It would be an act of supererogation, however, to dwell upon this subject before this enlightened audience.

Internal medication.—Every case of diphtheria, not presenting diarrhœal symptoms, receives a full dose of calomel, from four to eight grains, according to age. This is followed in six hours, if necessary, by a saline laxative in the mild tonsillar cases, while in the more severe types the action of the calomel is aided by ℥ j. to ℥ ss. of oil of turpentine. The latter usually produces several pultaceous stools. The gastro-intestinal tract is now prepared for the reception of food and the necessary medication; the temperature is usually reduced, and the patient's comfort enhanced. Hitherto these were the chief objects of the calomel treatment. We have now, however, another reason for its value, in the fact that calomel in purgative doses has been successfully used to abort other infectious diseases, as has been demonstrated by Ebstein and others. Clinical demonstration being the chief aim of this paper, I would adduce the testimony of Dr. Coester, in the *Berliner klin. Wochenschrift*, 1886, p. 55. The author himself took with good effect 1.0 gr. in three doses, and administered it in sixty-nine cases with eminent success in ameliorating the course of the disease. He had previously reported 298 cases, with 10 deaths, in various types of the disease, occurring during twelve years' practice; but in his last series of 69 cases he lost only one, a case of laryngeal diphtheria, without faucial deposit, which survived eighteen days after tracheotomy.

Tr. ferri muriatis is another remedy which I prescribe in all cases of diphtheria, not, however, in the small doses which I formerly used in combination with chlorate of potassium, but in doses from eight to twenty-five drops every hour, as we administer it so successfully in erysipelas. Only sufficient glycerine and water are added to somewhat soften its astringent taste; the more concentrated the better the local effect. It is administered two hours after the calomel, and continued hourly or bihourly night and day. I would lay stress only upon one point, unimportant as it may seem; *food or stimulants may precede the iron, but should never follow it immediately.* Then a local effect is obtained, which is readily recognized in the shrivelling of the deposit and the reduction of the circumjacent lividity.

The next remedy to which I would refer is *bichloride of mercury*, which is prescribed in all severe cases, especially when the uvula, nose, or larynx are involved. I will not weary you by entering upon a defence of this valuable agent, for many of you are doubtless familiar with it. I would refer, however, to the fact that I propose to present to you clinical evidence, not only to demonstrate its therapeutic value, but also the tolerance of large doses continued for many days without depreciating the system. I must say here, moreover, that there is no microscopic evidence to show that bichloride of mercury is injurious to the blood; while, on the other hand, we have the testimony of Keys that it increases the red blood-corpuscles. Nothnagel and Rossbach say: "It is not possible to consider the mercury as the direct cause of the wasting and anæmia. When the local disturbances are prevented by proper measures (such as purifying the mouth, cleansing teeth, and proper selection of preparation and form of administering) the treatment may be continued for a long time without any disturbance of nutrition. This testimony, which is corroborated by other modern investigators, should dispel the apprehensions still entertained by many regarding the spoliative influence of mercury upon

the system. In this connection a recent clinical report of J. Stumpf, in the *Muenchener Med. Wochensch.* (1887, p. 219), may be of interest. Having, during the early part of an epidemic, lost 22 out of 29 cases, Stumpf changed his treatment to inhalations of solutions of bichloride of mercury as the sole treatment, with the result of only 2 deaths in 31 cases. He administered with a hand ball-atomizer four grammes of the following solution: Hydrarg. bichloride, 0.2; aquæ destill., 170; and aqua menth., 30.0; using it every hour five times, then every two hours five times, then every three hours. The patients were children from nine months to twelve years, mostly from three to six years. There was one death from acute laryngeal diphtheria, without faucial deposit, and the other died in three weeks from diphtheritic neuritis. The temperature was invariably reduced, and a line of demarcation soon appeared around the deposit which began thus to exfoliate; the appetite returned. Every case was salivated, but this complication ceased three or four days after discontinuing the bichloride, under a three per cent. chloride of potassium mouth-wash. Roborant diet was given in all cases. This record would fortify the position I take, that bichloride of mercury does not depreciate the system in diphtheria.

The chief point to which I would direct your attention is my method of administration, which offers the advantage of the local effect upon the diseased surface of a 1 to 2,000 solution of bichloride without irritating the stomach. I order a teaspoonful of a solution of one grain to four ounces of water to be given every two hours. But this is always preceded five minutes by four to six ounces of milk or other nutriment. Thus the antiseptic solution is made to bathe the entire throat, and when it reaches the stomach it finds a diluent to neutralize its irritant effect. Neither water nor food is permitted for fifteen minutes. The nurse is cautioned against vomiting or diarrhœa, which indicates the immediate discontinuance of the mercury.

It will appear, then, from what I have said, that I lay great stress upon the proper administration and dosing of both the tincture of iron and bichloride of mercury. The nurse receives a written order of rotation as a lesson. The intervals are half hourly or hourly, as indicated by the nature of the attack, except when the patient does not readily fall asleep after being aroused for treatment. In this event an occasional longer interval of rest is permitted.

Rotation is as follows: First, stimulant, followed by tr. ferri; second, milk, followed by bichloride solution; third, other food, preceded by cleansing of mouth, applications of tripsin, or nasal injections, when indicated; fourth, begin as first.

Ice is applied externally to reduce glandular swelling.

I now desire to enlist your attention to a remedy which has but recently been added to the therapeutic armament against diphtheria. The remedies referred to above, viz., calomel, tincture of iron, and bichloride of mercury, have enjoyed the confidence of a large proportion of medical men since diphtheria became a recognized disease. Only the method of administering these remedies —a method which has slowly won my confidence—I have deemed worthy of presenting to your consideration. In oil of turpentine we have a more recent remedy, which, during the brief time of its clinical history, has been so thoroughly tested in private as well as in hospital practice that I must urge upon you its claim as a valuable agent in modifying and shortening the disease. If I enter somewhat at length into a discussion of the merits of oil of turpentine as a remedy in diphtheria, my reason lies in the fact that it is comparatively unknown as an internal remedy in this country, although its application in this disease originated here. In conversation with many colleagues, some of whom are specialists in paedriatics, I have not found one who has ventured to use it. They had read allusions to it in our journals, but all expressed appehensions lest the large doses required would produce untoward effects upon the genito-urinary organs. I may say that I shared these apprehensions in my earlier experience, but I was impelled to its use by the favorable reports in the German medical journals. In my first case I administered it per rectum with olive oil.

That the effect of large doses of oil of turpentine is not even unpleasant, my own experience in the thirty-nine cases of which I have notes, fortified as it is by the authors whom I shall quote, will, I trust, satisfy you.

In only one case have I observed temporary hæmaturia, in none strangury. This would seem the more remarkable, since experience teaches that the ordinary medicinal dose—ten to fifteen drops—does produce strangury. Last winter I ordered for a boy, eight years of age, suffering with typhoid fever, eight drops of ol. terebinth. every three hours. In two days the urine became scant and bloody. The classical report in George B. Wood's "Materia Medica" of a similar result on the crew of a ship laden with turpentine is perhaps familiar to you. That air charged with dry turpentine vapor will produce strangury and bloody urine is well brought out in the case (reported in the *Centralblatt für klin. Medizin*, No. 46) of a cooper who was repairing empty turpentine barrels in a close room.

A quotation from the "United States Dispensatory" may serve to allay apprehension with regard to the danger of large doses of oil of turpentine. "Swallowed in moderate quantities, it produces a sense of warmth in the stomach; accelerates the circulation. In small doses frequently repeated it stimulates the kidneys, augmenting the secretion of urine, and often producing, especially if long continued, painful irritation of the urinary passages, amounting sometimes to violent strangury. In large doses it occasions slight vertigo, a sense of fulness in the head, sometimes amounting to intoxication, attended frequently with nausea, and succeeded generally, though not always, by speedy and brisk catharsis."

To illustrate the tolerance of large doses of turpentine Bosse cites the experiments of Naunyn, made in 1868, to ascertain the conversion-products of turpentine in the human body. Naunyn and two other gentlemen took each one hundred grammes, about ℥ iij. of ol. terebinth. in emulsion with yolk of egg, in the course of four hours, with no unpleasant effect except slight headache. One of my nurses administered (by misconception of my orders) to a boy, ten years of age, one ounce of oil of turpentine, without unpleasant effect. I trust that these facts will dispel the fallacious ideas generally entertained regarding the danger of large doses of oil of turpentine.

Before presenting to you clinical evidence in behalf of this remedy, I desire to say that there is a strong scientific basis for its application in a zymotic disease like diphtheria. It has been shown by Koch that thymol and oleum terebinthinæ, being ozone-carriers, rank high as parasiticides. Indeed, so dilute a solution as 1 to 75,000 of ol. terebinth. will retard the development of anthrax spores. Grawitz and De Bary (*Virchow's Archiv*, No. 108, p. 88) say: "We undertook methodical investigations which demonstrated that oleum terebinthinæ is a germ-destroying agent of first rank, in many respects to be preferred to sublimate and carbolic acid. Turpentine can be as little rendered impure by pus cocci as the stronger solutions of sublimate and carbolic acid." As turpentine is eliminated by nearly all the secretions, it may be taken for granted that it circulates in the blood. Accepting the proportion of blood to the weight of the body as one to eight, we would have in a child of twelve years of age about ten pounds of blood. By administering one-half ounce oleum terebinthinæ we produce a solution of 1 to 320. Granting that gradual elimination will diminish this proportion, we may still claim that we obtain a sufficiently strong solution circulating in the blood to, at least, actively retard the development of disease germs. There is no other antiseptic by which a result approaching that from oleum terebinthinæ can be obtained.

Huebner says ("Schmidt's Jahrb.," 1884, 201): "The diphtheritic poison lies in the blood and intestines. From the latter parasites are constantly sent into the blood. This source should be destroyed. Hence, by disinfecting the intestinal canal by a large dose of ol. terebinth. in the early stage, we accomplish an important purpose."

The value of ol. terebinth. in inflammatory affections of the mucous membranes has been repeatedly attested by competent observers. A recent contribution to our knowledge of this subject is by M. J. Rossbach, who is well known as a cautious and skeptical investigator of the action of medicinal agents. He says: "Turpentine is the chief remedy in the diseases of the respiratory mucous tract. In watery solutions it increases secretion and diminishes engorgement by contracting the blood-vessels." The high esteem in which it was held by the older writers in puerperal fever, and by George B. Wood, and also by Graves (who administered it in drachm doses twice daily), in typhoid fever, attests its empirical value in low forms of disease. Clinical evidence, however, is the touchstone of its value in diphtheria, and this I propose to lay before you, to substantiate the view that in this harmless agent we have a new weapon with which to combat one of the most relentless foes of the human race.

I administer ol. terebinth. in doses of one drachm to half an ounce to children from six to fourteen years of age, once a day, oftener in cases demanding it. It may be given pure, followed by milk, or mixed with milk, or in emulsion. Vomiting occurs sometimes after the first dose, but it is usually retained afterward. On two occasions my hospital nurse, alarmed by the rapid spread of the deposit, administered an ounce to children of twelve and fourteen years of age, with good effect. In about fifty per cent. of the cases it produces a laxative effect; it always stimulates the secretions of kidneys and skin; the odor is quickly detected in these as well as in the fæces.

The originator of the turpentine treatment of diphtheria is Bosse (*Berl. klin. Wochensch.*, No. 43, 1880), who stumbled upon it by accident. (I may say here in parentheses that the value of large doses of merc. bichlor. in diphtheria was discovered, according to Dr. Armor, by a similar accident.) A boy, aged ten, who presented such well-marked symptoms of laryngeal stenosis that a fatal termination was imminent, was given by mistake twelve grammes of ol. terebinth., followed immediately, upon discovery of the error, by one-fourth litre of milk. The child, however, was not disturbed in the least; he grew quiet, and the cyanosis and sawing respiration disappeared. On the following morning the voice was still hoarse, but no longer toneless, the tenacious deposit was loosened—a marvellous change had ensued. Bosse, though skeptical and giving good reasons for being guarded in the statement, became convinced of its value after treating twenty-three cases, in children from two to twelve years of age, of severe diphtheria, without a death, while out of sixty-three cases treated previously by other measures, chiefly with chloride of potassium, four had died. He administered eight grammes to children of two to seven years of age, and twelve grammes to older children, pure, followed by milk, once a day. Deposit disappeared usually on the third day. In a second paper (*Ib.*, No. 10, 1881) Bosse details twenty cases, four of which were his wife and children. In these also the effect of shortening the most unpromising cases was remarkable. There were two deaths in three and twelve hours, respectively. In the literature of this subject I have encountered but one unfavorable report. Guttmann stated, in the discussion of Henoch's paper referred to above, that he had seen astonishing results from turpentine in one-drachm to two-drachm doses, but that later experience had disappointed him. I think his maximum dose was too small, and he erred in expecting a specific effect in all cases. On the other hand, we have abundant testimony from hospital and private records in favor of this remedy.

The *Deutsche Med. Zeitschrift*, 1883, p. 157, contains a paper read by Dr. Satlow before the Leipzig Medical Society. Satlow reports forty-three cases of the severest type of diphtheria, in which he followed Bosse's turpentine treatment with striking results, the mortality being three per cent. Three of his cases were laryngeal, which could not otherwise have escaped tracheotomy. A large proportion presented albuminuria, quite a number suffered from hæmaturia, which disappeared soon after omitting turpentine. Comparing the results obtained from the latter with his previous unhappy experience in this disease, Satlow confesses himself a convert to Bosse's method, when applied in the early stage. Satlow adds one gramme of ether to fifteen grammes of turpentine to prevent vomiting.

In the *Journal für Kinderkrankheiten*, 1885, Dr. Siegel, Chief of the Olga Hospital in Stuttgart, reports 83 cases of diphtheria, many of which were of the most serious type, being sent in by physicians when *in extremis*. Of 47 cases treated by turpentine, 14.8 per cent. died; of 16 cases treated by salicylic acid, 43 per cent. died; of 24 cases treated by sublimate (inhalations and brushing), 25 per cent. died.

In four cases sent to the hospital for laryngeal stenosis, tracheotomy was rendered unnecessary. In one case, when the former attendant appeared to witness the operation, he was surprised to find the symptoms so far ameliorated by a large dose of turpentine that the operation was not made. All the cases are cited in detail in Dr. Siegel's report.

Dr. Lunin's "Report from the Oldenburg Hospital for Children in St. Petersburg" (*Centralblatt für klin. Medizin*, 1885, p. 311) contains the following data regarding his treatment of diphtheria. Six different methods had been pursued in this institution:

1. Local, by 0.1 per cent. sol. bichlor. mercury, brushing the entire posterior wall of pharynx hourly.

2. Liq. ferri sesquichlor. internally, daily quantum 1 to 8 grammes in hourly doses, mouth and throat being cleansed by a three per cent. solution of boric acid.

3. Chinolin, 5 parts to 50, solution in alcohol brushed over membranes.

4. Resorcin pencilling, ten per cent. solution every two hours, and washing with one per cent. solution every hour.

5. Bromine, 1 to 200 solution for gums, and inhalations every hour of 0.2 to 0.4 per cent. solution for five minutes.

6. Turpentine, according to Bosse, either twice daily—one teaspoonful or ten drops hourly—three per cent. solution of boracic acid locally. As an average, the patients used 20 to 30 grammes turpentine, some 120 grammes. There was no strangury; it was omitted when vomiting or diarrhœa occurred. In all cases wine and musk were freely used. All the cases are reported in detail.

The statistics are as follows:

Fibrinous form.		Phlegmonous form.	
	Percentage of deaths.		Percentage of deaths.
Sublimate	30.2	Sublimate	45.6
Iron	31.6	Iron	56.3
Chinolin	32.6	Chinolin	53.0
Resorcin	20.6	Resorcin	65.0
Bromine	46.7	Bromine	69.7
Turpentine	8.3	Turpentine	43.4

The laryngeal cases are not included. That the average of the cases treated in this hospital is very severe is demonstrated by the total mortality, 55.8 per cent. in 410 cases. I cannot adduce my own statistics at this point because turpentine enters only as an important element into it. But reference to my clinical notes will show the indisputable value of this remedy in my hands. I trust that these data will encourage others to add ol. terebinth. to their list of remedies, and I would especially urge its administration early in the disease.

One more point, and I have done. It may be remarked that I have entirely discarded a remedy which has been, and is now, much in vogue. As mentioned above, *chlorate of potassium*, in combination with tincture of iron, had served me well until I encountered the more severe type of diphtheria. The quantity of both these remedies, as they are usually administered, is too small to make any very decided impression in these forms. A. Jacobi wrote long ago that the object in administering chlorate of potassium in genuine diphtheria is to remove the accompanying catarrhal condition, and he regards it as most efficacious only when the deposit is limited to the tonsils.

In the classical treatise on Materia Medica of Nothnagel and Rossbach, chlorate of potassium is referred to as "the most useful and best remedy that we possess for stomatitis mercurialis; but that the remedy is entirely useless in diphtheria, when given in ordinary doses, hardly admits of any doubt." As my own experience confirms this judgment, and as large doses of chlorate of potassium have been shown by Marchand, Hammake, Jacobi, and many others, to produce serious and even fatal renal disturbances, I feel constrained to discard this agent altogether in diphtheria.

I have now outlined the treatment of diphtheria as it has evolved itself in my experience by the light of modern therapeutics. The chief points emphasized by my clinical histories are:

1st. The necessity for local applications in the nasal and laryngeal form, and the inutility of these in most cases of the faucial variety.

2d. The administration of large doses of tincture of iron to saturate the system, instead of the small doses formerly resorted to.

3d. The value of full doses of bichloride of mercury in the more severe types, especially in the laryngeal.

4th. The value of large doses of oil of turpentine once a day in all severe types.

5th. The inutility of chlorate of potassium.

6th. The advantage of administering our remedies in such form and rotation as to obtain their local antiseptic effect in connection with their general effect.

The entire number of cases treated by the method above indicated was thirty-nine—thirty being in hospital, nine in private practice. Mild and doubtful cases are rigidly excluded from this record.

Among these thirty-nine cases there were two deaths, both in hospital practice; one occurred in sixty hours, and the other in fifteen days. In the first fatal case swallowing was so difficult that medication was not properly executed; in the second case the deposit disappeared so rapidly in three days that turpentine and bichloride were discontinued. Gastric irritability appeared several days later, when iron also was suspended. Patient died from neuritis.

It may be of interest to read a few brief histories illustrating the type of the disease I have observed, and the method and effect of treatment. I trust, Mr. Chairman, that these records may lead to the collective investigation alluded to in your recent circular.

Desiring to present the subject in perfect fairness before you, I will first cite the statistics of the consultation cases in which I suggested the treatment here referred to.

1. On December 8, 1883, was called by the late Dr. William Frothingham to see J——, a child, aged three, who had been sick three days; had been treated by iron and chlorate of potassium, also one dose of subsulphate of mercury as an emetic, when laryngeal stenosis commenced. Advised ol. terebinth.; one drachm was administered per os and two per rectum, neither of which was entirely retained. I performed tracheotomy, which had become imperative, but without avail. Patient died on following day.

2. Miss H——, aged eight. Saw her with Dr. L. Waldstein, the attending physician, at 9 A.M. of December 10, 1885. She had been ill two weeks. Stenosis was not pronounced, voice lost, deposit disappearing from throat. Advised ʒ j. ol. terebinth., which was retained. At 4 P. M. Dr. Waldstein regarded tracheotomy necessary. Patient died immediately afterward.

3. F——, boy, aged nine, living at Stamford, Conn.; seen with Dr. Hungerford on November 16, 1887. Had hoarse cough several days, but no deposit. Croup ensued, whereupon Dr. Hungerford, anticipating diphtheria, which was at that time prevailing in Stamford, administered tincture of iron in ten-drop doses, and one dose of ʒ ij. ol. terebinth. Next day symptoms aggravated; stenosis pronounced but paroxysmal. Bichlorate of mercury, $\frac{1}{32}$ grain, every two hours added, and ʒ ij. turpentine again administered in emulsion, and inhalation of turpentine vapor. Later in the evening Dr. Hungerford made a tracheotomy, with great relief. On following day I saw the boy again, and found deposit on uvula and pharynx. Iron, bichloride, and turpentine continued. Patient was comfortable.

November 18th.—Saw patient again, with Dr. Hungerford. *Deposit had disappeared from throat.* Great dyspnœa having occurred during the previous night, Dr. Hungerford had removed the tube, and with an aspirator and catheter removed a quantity of dried crusts and some membrane, affording great relief. Same treatment was repeated in my presence, because dyspnœa had recurred. Only crusts were removed. Patient immediately fell asleep. But dyspnœa again returned at night, which could not be relieved by aspiration. In this case the faucial deposit had disappeared as soon as the system was brought under the influence of the combined treatment. Dr. Hungerford attributes the death to blocking of bronchiæ by dried crusts.

Clinical histories.—Josephine K——, aged seventeen, admitted to hospital of New York Juvenile Asylum, June 8, 1887, at 12 M. Temperature, 100°; pulse, 120, feeble; bowels and kidneys acting; deposit on pharynx as far as visible; tonsils, palate, and anterior pillars enormously swollen, and presenting appearance of bacon rind. Extremely offensive odor from mouth; cervical glands so swollen that the chin is even with the chest. Sleeps constantly; entire body cyanotic; respiration is not embarrassed. Treatment: Calomel, eight grains, followed in four hours by ʒ iij. ol. terebinth.; bichloride of mercury, $\frac{1}{32}$ grain; of tincture of iron, twenty drops. Stimulants and nutriment in half-hourly rotation. Swallowed with great difficulty.

June 9th, 4 A.M.—Temperature, 103°; pulse, 130, flickering; somnolent; cyanosis deepening.

June 10th, 9 A.M.—Temperature, 104°; pulse, 140. Continued to fail until 10 P.M., when she expired. She retained first dose of turpentine, and very little of other medicines, etc.

Viola R——, aged three. First seen March 3, 1885. Temperature, 103°; deposit abundant on both tonsils. Calomel, four grains; tincture of iron and chlorate potassa mixture every half hour, alternating with milk; tripsin solution locally by brush every hour.

March 6th.—Deposit unchanged, a new spot on uvula. Enema of ʒ ij. ol. terebinth., with ℥ j. starch paste added.

March 9th.—Deposit flaking off.

March 20th.—Iron, chlorate of potassium, and tripsin having been continued deposits gradually disappeared.

March 23.—Dismissed.

Louise P——, aged eleven, March 21, 1886. Pharynx, velum, tonsils, and nose affected. Calomel, followed by tincture of iron in ten-drop doses, alternating half-hourly with $\frac{1}{32}$ grain bichloride of mercury. Nose treated by papayotin solution, ten per cent., in glycerine, and syringing with 1 to 10,000 bichloride solution. Food and stimulants, *p. r. n.* Three doses of ʒ j. turpentine, pure, were administered in three successive days without effect on disease; one dose vomited. Was seen several times by Dr. A. Jacobi. She made a very tedious recovery in one month.

Howard P——, aged three, brother of preceding pa-

tient; March 22, 1886. Pultaceous deposit on left tonsil; ℥ j. turpentine, pure, followed by milk, retained. Tincture of iron, six drops hourly.

March 23d.—Deposit disappeared.

March 24th.—Deposit on right tonsil appeared. Turpentine is now vomited; hence discontinued.

March 26th.—No improvement; bichloride of mercury, $\frac{1}{40}$ grain, added hourly.

March 29th.—Deposit disappeared, patient improving.

March 30th.—Voice husky, stridulous cough. Dr. Jacobi saw patient. Calomel, four grains, and constant inhalation of turpentine added. Remained all night, prepared for tracheotomy.

March 31st.—Improved.

April 14th.—Dismissed, with paralysis of velum.

Conrad L——, aged nine, admitted to hospital February 9, 1887; deposit on both tonsils. Calomel, five grains, followed by Rochelle salts. Tinct. ferri and chlorate potass mixture.

February 12th.—Deposit on velum. Tinct. ferri, ten drops, alternating with bichloride mercury, $\frac{1}{32}$ grain, every half-hour.

February 14th.—Complete aphonia; stridulous cough; marked pallor; some dyspnœa; no cyanosis. Inhalations of turpentine and lime-water vapor without intermission. Treatment continued, stimulants and nourishment as required (and given in all cases reported) until February 20th, when patient became cheerful and began to notice his surroundings; voice returned on February 25th. Dismissed, March 10th.

Jennie L——, aged thirteen, admitted March 15th, with large deposits on both tonsils; rapid pulse; marked asthenia. Calomel, six grains, followed by ℥ ij. ol. terebinth. in six hours; tincture of iron and bichloride alternating hourly; ℥ ij. turpentine once a day. Dismissed, March 20th.

Hattie F——, aged seven, admitted April 17th. Deposit on velum and right tonsil. Calomel, four grains, followed by Rochelle salts; tinct. ferri, twelve drops, and bichloride mercury, $\frac{1}{32}$ grain, hourly; daily dose of ℥ j. turpentine until April 23d. Dismissed, May 1st.

Maggie P——, aged six, admitted May 28th. Deposit on uvula, pharynx, tonsil, and in nose simultaneously. Calomel, four grains, followed by ℥ j. turpentine. The latter was continued once daily, and tinct. ferri and bichloride mercury hourly. Nose syringed three times daily with 1 to 8,000 bichloride solution, preceded two hours by fifteen per cent. tripsin solution. Dismissed, June 15th.

Charles A——, aged twelve, admitted May 19th. Deposit on tonsils, pharynx, velum. Calomel, six grains, followed by one dose of three teaspoonfuls of turpentine. The latter was continued once daily for one week; also hourly doses of tincture of iron, fifteen drops, and bichloride mercury, $\frac{1}{32}$ grain. Discharged, June 8th.

Allen F——, colored, aged twelve, admitted May 28th. Tonsils, pharynx, and palate affected. Calomel, four grains, followed by turpentine, ℥ iij.; tincture of iron, twelve drops; and $\frac{1}{32}$ grain bichloride, hourly; ℥ iij. turpentine once daily for five days.

Minnie P——, aged eleven, admitted June 3d. Temperature, 104°; pulse, 130, feeble; glands enormously swollen; deposit on tonsils, velum, and in nose. Ordered six grains of calomel, followed by turpentine, ℥ ij., bichloride and iron, hourly; turpentine ℥ ij. once daily; nasal injections of bichloride, 1 to 8,000. Discharged, June 18th.

John Van D——, colored, aged thirteen, was in hospital last winter for double pneumonia, from which he barely escaped. During this attack he suffered from suppression of urine for forty-eight hours, which was relieved by nitro-glycerine. Admitted June 17th, at 3.30 P.M. Temperature, 103.5°; pulse, 130. Diagnosis: Follicular tonsillitis, no pure diphtheritic deposit being visible. Temperature at 7 P.M., 105°. Calomel, eight grains, moved bowels. Chlorate of potassium and iron mixture hourly; milk and stimulants.

June 18th, 8 A.M.—Temperature, 104°. Noon: temperature, 105°; pulse, 135. No deposit; patient somnolent.

June 19th, A.M.—Temperature, 103°. Evening: temperature, 104°; pulse, 120, feeble. Large pultaceous deposit covering entire left tonsil and fading into pharynx; left cervical glands enlarged. Ordered tincture of iron, fifteen drops, and bichloride mercury, $\frac{1}{32}$ grain, alternating hourly. The deposit was rapidly spreading and patient's condition alarming. The nurse administered (by misconception of my orders) ℥ j. ol. terebinth., pure, followed by milk.

June 20th.—Continues somnolent. Morning temperature, 102°. Turpentine has moved bowels once. At 2 P.M. I found a new deposit on right tonsil; temperature, 101°. Ordered ℥ ss. turpentine; other treatment continued.

June 21st.—Took ℥ ss. turpentine at 6 A.M.; deposit on right tonsil shrivelling. Vomited last dose of turpentine. Still somnolent.

June 23d.—Deposit disappearing in flakes from right tonsil; temperature, 101°. Despite daily dose of ℥ ss. turpentine and hourly dose of tincture ferri and bichloride mercury, he required ℥ iij. Rochelle salts to move bowels. No deposit on left tonsil.

June 24th.—Temperature, 99°. Omit bichloride and turpentine. Discharged, June 28th.

Wm. R——, aged ten, admitted June 8th. Morning temperature, 102°; pulse, 130, weak; deposit thick on both tonsils; cervical glands swollen; entire aspect of case unpromising. Calomel, five grains; tincture of iron, twelve drops; bichloride of mercury, $\frac{1}{32}$ grain, every hour.

June 12th.—No change on tonsils; new deposit on palate; glands larger; somnolent; patient failing. Nurse gave him ℥ ij. turpentine, which moved bowels three times.

June 13th.—Temperature, 102.5°; pulse, 105, stronger; patient looks brighter; deposit on tonsils shrivelling.

June 14th.—Turpentine, ℥ ij. at 6 A.M.; moved bowels at 1 P.M.

June 15th.—Deposit disappearing.

June 16th.—℥ j. turpentine.

June 17th.—No deposit. Discontinue bichloride and turpentine. Continue iron. Dismissed, June 21st.

This was, like the last, a serious type. Turpentine was begun when deposit appeared on palate. Deposit on tonsils began to shrivel in twenty-four hours, and disappeared in four days.

Edward V——, aged thirteen, admitted June 16th. At 8 A.M., temperature, 105.5°; at noon, temperature, 104°; pulse, 130; appears to be a pure case of follicular amygdalitis of both tonsils. Ordered calomel, six grains, iron and chlorate of potassium mixture.

June 17th.—Temperature, 100°; pulse, 100. There is now a thick pultaceous deposit on left tonsil. Ordered turpentine, ℥ ss.; bichloride and iron hourly.

June 18th.—Nurse having noticed fresh deposit on uvula and general condition depreciating, administered ℥ j. turpentine; temperature, 102°.

June 19th.—*Deposit entirely disappeared.* Temperature continued above normal until June 23d, when patient was dismissed.

Frank F——, under care of Dr. F. H. Daniels, aged fourteen, admitted to the hospital June 16th. Deposit pultaceous on both tonsils. Ordered calomel, five grains, followed on following morning by ℥ ss. turpentine. Bowels moved in three hours.

June 18th.—No change. Ordered ℥ ss. turpentine; tr. iron and bichlo. merc. hourly.

June 20th.—Same treatment. In the afternoon, bowels not having moved in three days, patient received a teaspoonful of Rochelle salts. *The urine became bloody*, and remained so until the 24th, without strangury. Deposit cleared gradually. Dismissed, June 29th.

George M——, colored, aged eight, under care of Dr. Daniels. Admitted to hospital June 5, 1887. Temperature, 101°; pulse, 108. Deposit on portion of pharynx, uvula, and both tonsils thin. Ordered six grains calomel, followed by 3 j. turpentine in six hours, which moved bowels. Iron and bichlo. every hour.

June 10th.—Has taken 3 j. turpentine daily; also iron and bichlo. every hour. Deposit disappearing.

June 11th.—Continue iron alone; deposit less.

June 12th.—Nausea and vomiting; bowels constipated; enema.

June 13th.—Iron discontinued; food and stimulants in smaller quantities; pulse rapid; temperature, 100°; enema.

June 14th.—Vomits less; temperature normal; pulse rapid and feeble.

June 18th.—Patient vomits occasionally, but retains a fair amount of nutriment.

June 20th.—Taking food and stimulants freely. Small deposit on uvula. Died of heart failure.

Frederic W——, aged twelve; admitted June 10th. Temperature, 102°; pulse, 112. Deposit slight, on right tonsil. Ordered calomel, six grains, which moved bowels in six hours.

June 11th.—Temperature, 100°; pulse, 112. Tr ferri, ten drops, every two hours.

June 14th.—Fresh deposit on left tonsil and uvula, with surrounding livid area. Temperature, 102°. Case rapidly assuming grave aspect. Ordered ʒ ss. turpentine; also, hourly, bichloride and iron.

June 15th.—Temperature, 99°; pulse, 98. Deposit unchanged.

June 16th.—Temperature normal; deposit shrivelling; no lividity.

June 17th.—Deposit disappeared. Continue iron alone. Dismissed, June 24th.

Hermann D——, aged thirteen; admitted June 20th. Temperature, 100°; pulse, 120. Ulcer on right tonsil, diphtheritic deposit on left. Ordered calomel, six grains, followed by Rochelle salts. Tr. iron, ten drops, every hour.

June 21st.—Deposit spreads; general condition worse. Ordered ʒ ss. turpentine; moved bowels twice.

June 22d.—ʒ ss. turpentine; nauseated him.

June 24th.—ʒ ss. turpentine; vomited. Continue iron alone. Dismissed, June 25th.

Katie H——, aged fourteen; admitted August 16th. Temperature, 103°; pulse, 120. Large deposit on both tonsils. Ordered calomel, five grains, followed by salts. Tr. iron and bichloride hourly.

August 17th.—6 A.M.: Deposit appearing on palate, nurse became alarmed, and gave 3 vj. turpentine, which opened bowels once.

August 18th.—Temperature, 99°; deposit shrivelling. Ordered ʒ ss. turpentine.

August 19th.—Temperature normal; no deposit. Dismissed, August 26th.

Sadie S——, aged eight, daughter of gentleman occupying cottage at Long Branch, was seen on July 2, 1886. She had been under treatment by her city physician for follicular tonsillitis. She now presents large deposit on right tonsil; palate livid; temperature, 103°; cervical glands swollen on both sides. Calomel, four grains, tinct. ferri and chlorate potass every half hour.

July 3d.—No change. In the afternoon was suddenly called; found her hoarse, with stridulous cough; nostrils distended; sawing respiration; face pale and anxious. Ol. terebinth. 3 ij. in milk at once. Bichloride alternated with iron and potass mixture. Dr. Andrew H. Smith saw her four hours later with me; he discovered deposit in larynx. Treatment continued, with addition of turpentine and lime-water inhalations. Intubation instruments telegraphed for, and preparation made for tracheotomy. On following morning Dr. Froehlich, the family physician, arrived, bringing Dr. Frederick Lange with intubation instruments. But the patient was completely relieved of laryngeal stenosis, and deposit had almost disappeared, only whispering voice remained. Instruments were kindly left by Dr. Lange to meet possible return of stenosis.

July 5th.—Deposit entirely disappeared. Inhalations continued a week. Patient did not recover her voice until after convalescent two weeks.

These cases are representative of the remainder on my records, which it would be but reiteration to cite.

THE MECHANICAL TREATMENT OF SPINAL IRRITATION.[1]

By W. B. DE GARMO, M.D.,

NEW YORK.

Many authors have questioned the existence of any distinct disease worthy of the title of spinal irritation, and have attributed all symptoms usually so designated as due to hysteria, intercostal neuralgia, myalgia, or other causes.

It matters not whether you call these cases spinal irritation, spinal weakness, spinal tenderness, posterior spinal anæmia, hyperæmia, or, if you choose, hysteria; as a distinct and easy recognizable class they certainly exist, are frequently met with, are not much benefited by drugs, and they have a strong tendency to become bedridden.

The natural classification of this disease would bring it within the exclusive field of neurology, but this paper, while it does not pretend to discuss the subject in a scientific manner, does attempt to show, by the relation of a few cases treated, that more can be done for these patients by the orthopedist than can be accomplished by medication.

In the following cases it will be noticed that most of them have passed through about the same routine treatment, without relief, and it is equally noticeable that improvement under mechanical treatment has been almost universal.

The single case in which there was no benefit experienced should undoubtedly have been excluded from this list, but as its treatment was begun under the belief that it was a case of spinal irritation, the history and failure is given.

Case I.—Mr. T. G——, single, aged thirty years, of Scotch parentage and with a good family record, gives the following history:

He believes that his present condition is due to a fall in boyhood, but he enjoyed good health for four years after this, before the occurrence of any of his spinal troubles.

He then had what appears to have been an attack of inflammatory rheumatism, with two or three recurrences at later dates.

When twenty years of age he developed severe pains in the chest, abdomen, and back, which were attributed to rheumatism by his attending physician; some tenderness in the upper dorsal region was also noticed, and sharp attacks of pain were usually followed by partial loss of power.

Any over-exertion was followed by extreme backache and headache, with great prostration and nervous irritability.

In this condition the patient was confined to his bed most of the time for fully six years.

There was no change in the mental condition of this patient, as is evidenced by the fact that during this entire period he supported himself by writing stories and doing fine lace-work.

During these years he was treated for almost every disease in the catalogue, and among the numerous remedies tried were hot applications of spirits of turpentine,

[1] Read before the Orthopedic Section of the New York Academy of Medicine, November 18, 1887.

croton oil, issues kept in his back almost constantly for three years, fly-blisters, ergot, belladonna, iodide of potassium, iodide of iron, morphia, strychnia—all with little or no benefit.

When the case came under my observation, in December, 1878, the following condition was presented:

Patient in bed most of the time, and suffering very little pain when he kept quiet; tenderness upon pressure along the spine from the first to eighth dorsal vertebræ, the most sensitive spot being in the region of the fifth and sixth. Complete anchylosis of both hip-joints had occurred during his long confinement in bed; general muscular system in as good condition as could be expected under existing circumstances.

A spinal support, similar to that which I shall show later, was applied, and simple tonics prescribed.

The subsequent history can be briefly told. In one month he was about the house the most of every day, and within the first six months was enabled to take drives of some distance. Occasionally he would overdo, and suffer from a return of his head and back ache for a few hours.

After eighteen months' use of the appliance he was practically cured of his spinal trouble, and although he has, during the past seven years, led an active life and done a large amount of mental work, he has had no serious relapse. On several occasions, however, after overwork, he has found it advisable to return to the use of his spinal support for a brief period.

Case II.—Miss G——, aged twenty-five. This young woman, soon after an unfortunate love affair, developed backache, headache, and obscure abdominal symptoms, and soon after became bedridden, or at least spent the greater part of her time in bed.

I saw her first on June 22, 1880. She had been at that time over one year in bed, and had been put through quite a severe course of pessaries and other treatment for supposed uterine displacement or ovarian irritation.

She complained mostly of backache following attempts to sit or walk. Her hair had become quite gray for so young a person, but in other respects she had the appearance of good health. Menstruation was normal and bowels regular.

Examination of the spine revealed the fact that pressure upon the spinous processes of the ninth and tenth dorsal produced intense pain and nausea.

While there was at times considerable pain in the ovarian region, no unusual amount of sensitiveness could be discovered at this examination.

A spinal support was applied, and a rapid recovery resulted; within six weeks after the support was applied the young woman came from her home in Elizabeth to see me. The instrument was worn about one year, at the expiration of which time she was able to leave it off, and has had no return of her former trouble.

Case III.—Miss M. R——, twenty-two years of age, had been strong and healthy up to two years ago, when, without known cause, she began to have backache, which gradually increased in severity until she has of late spent most of her time in bed. She has also suffered from neuralgic pains in the chest and abdomen.

Riding in any conveyance, walking, or doing almost any form of work about the house, is quite sure to bring on an attack which prostrates her for several days, and is attended by some loss of power.

At this examination, January 15, 1881, I find her in bed, complaining of no pain when perfectly quiet, but very sensitive to any sudden movement, and to unusual noises.

Examination of the spine shows great sensitiveness in the upper dorsal region. Pressure upon the spinous processes of the vertebræ of this region produces sharp pain and faintness.

The spinal support was applied, and a gradual, but complete cure resulted.

The following are her own words regarding her improvement after she had worn the brace about two years.

"You ask if I have been benefited by the brace. I know that I have, and, had I not had it, I would now be unable to walk. I am now gaining my former health, can go about the house, and do all kinds of light housework. I am able to walk, and ride every day that weather permits."

At a later date this patient left the instrument off, and has enjoyed uninterrupted good health.

Case IV.—Miss C. H——, aged twenty-six; spinal irritation with partial loss of motion.

The duration of present illness is about ten years, beginning with a sharp attack of malaria and two severe chills daily. This malarial condition continued with more or less severity for about two years, reducing the patient's general health very much.

Lack of muscular power was then noticeable, with extreme tenderness along the spine and sides.

The head dropped forward from muscular weakness, and the prominence of the seventh cervical vertebra was mistaken for an abscess and deformity resulting from Pott's disease. The tumor was painted with iodine, poulticed, and at one time an operation upon it was seriously contemplated by the physicians then attending her.

Plaster-jackets and various appliances were used in treating the supposed carious condition of the vertebra. She found considerable relief in the use of any appliance which gave her support and kept the spine comparatively quiet, but from the expense involved in frequent changes of spinal jackets, and owing to the great weight of the mechanical support applied, she has abandoned all modes of treatment, and now relies upon a corset with side-supporting crutches devised by herself.

I do not think that a single remedy that was ever used for any form of spinal trouble has escaped trial by one or more of the eight or ten physicians who have attended this young woman.

Cups, leeches, actual-cautery blisters, iodine, electricity, externally.

Cod-liver oil, strychnia, phosphorus, ergot, belladonna, quinine, iron, zinc, and a long list of tonics, internally, all without improvement.

The gynecologist has also treated this case for some suspected version or flexion, hyperplasia, or erosion. Whether one or all were present, the fact remains that the patient was not relieved.

As now seen, February 24, 1884, the patient is a confirmed invalid, without a shadow of hope of ever again leading an active life. She has spent the greater part of her time in bed for the past seven years, and for two years has not walked. Has not been out of her room for eight months. Sits up only about one hour during the day, and the least excitement, the call of a person not seen every day, any unusual or unexpected occurrence, will be followed by the most intense head and back aches, which prostrate her for several days, and are followed by an aggravation of all of her symptoms.

The back is at all times quite sensitive to pressure and the seat of much pain, both in the sacro-lumbar and upper dorsal regions.

Sudden movement or jarring produces the most severe pain. Bowels torpid; menses and all other functions normal. There was partial loss of motion in the lower extremities.

In this case there were two distinct sets of symptoms, arising from the two points of irritation.

The tender point at the upper dorsal region gives rise to sharp attacks of pain in the chest and hypogastrium, which were variously diagnosed and treated as indigestion, heart-disease, and incipient tuberculosis, while the point at the sacro-lumbar junction gave rise to pelvic symptoms simulating uterine or ovarian disease.

An instrument similar to that which I shall show you

was applied, and while recovery has been slow in this case, when its extreme character is considered it is one of the most satisfactory cases that I have seen. Benefit was experienced almost from the first, and her history is one of steady recovery.

The following extract from her letter, received about two weeks since, briefly tells her present condition.

"You would like to hear how well I am getting, I know. I can walk all around the house and yard, have gone out calling on the neighbors, and can ride nine miles without feeling tired. I can do almost any kind of house-work, and really feel quite well again."

The incorrectness of the first diagnosis of Pott's disease is now beyond all question, as the head is held perfectly erect, the neck is freely flexible, and there is no unnatural prominence of the seventh cervical vertebra, results which would have been impossible had caries existed.

Case V.—Miss G——, aged twenty-two, seen October 10, 1885. About five years since the patient had a fall which shocked her very much, and soon after she developed obscure nervous symptoms, followed later by severe trouble with the head and spine, which seemed to be of an inflammatory character, and necessitated three weeks' confinement to bed; since that time she has never been entirely free from her present symptoms.

She has what she calls "spinal headaches," the pain beginning in the back and gradually extending up to the head. Inability to sit or stand any great length of time, and spends most of her time in bed. Is very sensitive to sounds of any sudden nature; the slamming of a door causing nausea and even vomiting. Slightly emaciated, appetite and digestion poor.

Pressure upon the sixth to eighth dorsal vertebræ causes pain and nausea. Patient also has some uterine trouble, the exact character of which I have not ascertained, for which she is under treatment.

The spinal support was applied, and considerable benefit has been derived from its use, but a complete cure has not as yet been obtained. I have not heard from this patient during the past year, and cannot report her present condition. My last entry, November 16, 1886, states that she is improving, and is to continue the use of the brace.

Case VI.—Mrs. E——, aged twenty-eight, has been five years married, and is the mother of three children.

About four years ago she began to develop unaccountable nervous symptoms, and a little later discovered great tenderness along the spine at the upper dorsal region; has head and back ache beginning in the back and extending to the head; has indigestion, and is unable to stand long; suffers from slight uterine derangement, which is recent, and believed to have its origin in child-bearing. The supposed cause of spinal trouble is overwork.

A spinal support was applied to this patient on October 20, 1885, which soon relieved the head and back symptoms, and improved her general condition.

This patient was not seen again until one year later, when she came to me complaining of a slight return of her old trouble.

Upon examination it was found that the appliance was very much out of repair, and failed to give the support that it had at first given, while it gave unnecessary discomfort.

The instrument was put in order, and improvement from that date was again quite marked. At last accounts she was much improved, and contemplated leaving off the support.

Case VII.—Miss A. P——, twenty-eight years of age, has been a confirmed invalid for eight years; has been treated for heart disease, gastric trouble, paralysis, uterine displacement, and irritable ovaries.

Materia medica seems to have been exhausted upon her, and still her decline has been progressive and unchecked.

In this case there is loss of power to quite an extent both in the upper and lower extremities; the speech is defective, slow, and hesitating; digestion poor; bowels obstinately constipated; is subject to headache, and some backache—the latter is not, however, a marked symptom; tenderness is slight and along almost whole length of spine; muscles of back are so weak that patient cannot sit erect without leaning against something.

Support applied, May 29, 1886. As originally applied, the patient could not wear the brace, and it became necessary to abandon the upright steel spring, using instead a broad piece of canvas around the back attached to the side-posts. This instrument has now been worn for nearly eighteen months and aids her in sitting up, but she is no better, and there appears to be no tendency toward recovery.

Case VIII.—Mr. D. M——, aged thirty-one. One year before this patient was seen he developed severe back and head aches, with very little loss of power, but an indisposition to take any active exercise, for fear of bringing on an attack of pain. Has spent the most of past year in bed, sitting up occasionally for a short time only. Extreme tenderness is found in the upper lumbar region upon pressure. Has had a plaster-of-Paris jacket applied, and derived some benefit from its use, but as it was applied by a novice it soon became unbearable, and was removed.

A support was applied on October 15, 1885. Improvement was decided from the first, and has been progressive to the present time, when patient considers himself well, and the instrument is worn only part of the time.

Of the eight cases reported, six have been practically cured, one has been benefited and was, at last report, still improving. In one case mechanical support seems to have had no curative effect, but enabled the patient to sit up with increased comfort.

Six of the cases were females, two males. In six the disease originated between the twentieth and twenty-fifth years, one at nineteen, and one at thirty years of age.

The assigned causes were: Two from falls followed by shock; one from malaria; one from grief; one from overwork; and three from unknown causes. As regards the region of the spine affected, in four it was in the upper dorsal; one of these had an additional point in the lower lumbar region, in another it was confined to this locality; in two the lower dorsal was affected, and in one there was general tenderness along the whole spine.

In the one case where no benefit has been derived from the use of the appliance, I am now convinced that I was in error as regards the diagnosis. I do not believe that it properly belongs to the cases now under consideration, but that there exists more serious disease of the cord.

The appliance used on these cases is shown in Figure 1.

It consists of a pelvic spring arching over the crest of the ilium, which forms its base of support; when locked in front this spring maintains its position and cannot slip lower.

From the top of the arch of this spring a steel side-post runs to each axilla, and there supports a crutch-piece or shoulder-bow which passes across the back.

In the back, running from the pelvic spring to the shoulder-bow, is a flexible steel spring which carries the spinal saddles or supports.

Any number of saddles may be added that is deemed advisable, and in one case it was found desirable to have one support above the shoulder-bow.

This instrument has only one fastening, that being in the front of the pelvic spring, and the chest and abdomen are left entirely free from any compression. In this we have what is practically a splint for the spine; it is somewhat flexible, but gives sufficient support without restraining the ordinary use of the muscles. It belongs, as most of the members know, to the old system of Banning supports.

After all active symptoms of spinal irritation have subsided, I put on, in place of the instrument already described, a much lighter one, shown in Figure 2.

As there shown, it has only one saddle, but more can be added if indicated. The instrument has a light pelvic band and shoulder-bow, and no side-posts.

It is the same that I frequently advise for the correction of so-called round shoulders.

In the cases related, three wore their supports at night during their early treatment, believing that they rested better with them on; the others wore supports during the day only.

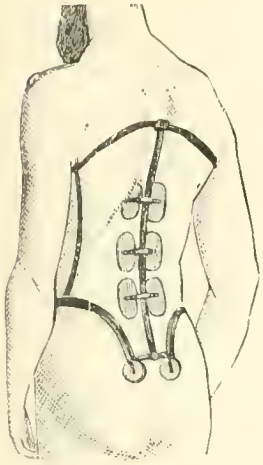


Fig. 1.

Fig. 2.

Where extreme sensitiveness existed, there has been apprehension on the part of the patients that they could not tolerate the pressure of the instrument in its immediate vicinity. It has been found, however, that, almost universally, the continuous and firm pressure given by the steel spring was, after the first day or two, a source of comfort rather than discomfort, and the disappearance of this tenderness has been one of the first signs of improvement; I have never seen a case where the pressure could not be tolerated after one or two trials.

Systematic and progressively increased exercise has been urged in every case; they have been asked to do just a little more each day than done on the previous. In fact, it has been the object to carry them to the full limit of their endurance, but not one particle beyond. Regarding this, extreme caution has been found necessary.

As regards medication, these cases have had, aside from meeting incidental symptoms, the hypophosphites of iron, lime, soda, quinia, and various tonics. Electricity has been tried, but the results were not satisfactory.

I am well aware of the fact that nearly all neurologists disapprove of the mechanical treatment of spinal irritation, but, so far as my inquiries have gone, I am led to believe that such disapproval is based upon routine practice, and not upon actual experience.

My own experience, and the experience of some of my orthopedic friends, leads to quite different conclusions, and this fact prompts me to bring the subject before this section of the Academy for discussion.

Brouardel on Typhoid Fever.—In an address delivered before the Hygienic Congress at Vienna, M. Brouardel, of Paris, described typhoid fever as more dangerous to man than cholera. He attributed its production to water-pollution in at least eighty per cent. of all cases. Attention to a pure water-supply is an all-important consideration in respect to its prevention. He believed it still an open question how far the origin of the disease was in decomposing organic matter, or whether there existed a specific typhoid germ.

Clinical Department.

A CASE OF REYNAUD'S DISEASE

By J. L. TRACY, M.D.,

TOLEDO, O

Ten years ago a young woman, aged eighteen, came to me and asked treatment for what I diagnosed at the time to be rheumatoid arthritis. The left shoulder-joint was firmly anchylosed, and the muscles of the shoulder were so much atrophied as to make a difference of one and a half inch in the measurements of the lateral halves of the body.

The singular feature of the case at that time was that the disease had advanced to the stage in which I found it without having prevented her from attending to the usual work of the house. She had never suffered pain, and did not know that the shoulder-joint was immovable. The atrophied muscles allowed the scapula increased mobility, which compensated the shoulder-joint anchylosis.

She had just finished learning the dressmaking trade, and the difference in measurement of the sides of the body that was revealed to her when being measured for her dress was what alarmed her, and caused her to seek treatment. The functions of the body were being performed in a healthy manner. She had several brothers and sisters; her parents were living, and all were healthy.

I had not seen the woman for a long time, when, six months ago, she came to me for treatment for her sore fingers and a sore toe. Her general appearance did not differ materially from her appearance when I last saw her. Anchylosis and atrophy were the same. Menstruation scanty, though regular. Bowels constipated; had headache a good deal of the time; was troubled frequently with sleepiness for several weeks at a time. She is of a bright, cheerful disposition; had the color of health in her face. She had not married. The nails were gone from middle finger and thumb of the left hand, and from the index, middle, and third fingers of the right hand, and also from the third toe of the left foot. From some of the fingers the skin was also gone; the denuded, ulcerating surface upon the first finger extended into the palm of the hand. The extremity of another finger was covered with a thin, shiny skin, bluish-purple in color, and the nail could be seen forming. Upon another finger a minute pustule showed itself, looking just as the skin does when the surgeon's needle is about to pass through it from within outward. From one of these pustules, she told me, the trouble always begins. The pustule would rupture, and a very small drop of sero-pus could be squeezed out, after which the pus would burrow beneath the skin at the edge of the pustular wall, and gradually loosen the skin from its attachment. The rapidity with which this ulceration advanced varied somewhat; but usually the nail and skin from one-half of the finger would be gone within two weeks. Sometimes the trouble would seem to spend its force when only one-third of the finger had been denuded, while at other times it would involve the entire finger. The nail was almost always destroyed. New skin would begin to form at the starting-point of the pustule very soon after it had ruptured, so that by the time the ulceration had ceased spreading, and sometimes before that time, the same shiny skin would be formed upon that part of the finger which was first affected. The fingers were never very painful, neither were they very tender, even when sorest. The history of the present trouble is that about seven years ago the patient pricked the index-finger of the left hand with her needle, and, instead of recovering as like injuries had done many times before, a chronic inflammation of the finger followed, with, in the course of a few, weeks a loss

of integument and nail, and the finger became a raw, bleeding surface, and so remained for nearly a year. The nail upon this finger has ceased to form, the matrix having been destroyed several years ago by the repeated ulcerations. The other fingers have become sore since this finger was injured; the last one became sore about six months before I saw her. The initial sore, in each case, seemed to follow some slight injury, and the course that the trouble followed was always the same as that above described, with the exception that sometimes the nail would be lost, and the sore would heal again within a few weeks, instead of lasting for a year, as did the first. There is no regularity as to the time when the fingers become sore, after having been once healed; neither does the outbreak follow as the result of some injury. The pustule shows under the nail sometimes, and upon different parts of the finger at other times. The fingers may all be sore at once; and, again, two or three may be well at the same time. None of the fingers has remained well for a longer time than three months. Only one toe has ever been sore, and that has the same history as the fingers. During the time that she was under my care, I thought that I could notice that the fingers were worse immediately after each menstrual period. I tried, in my treatment, to correct the amenorrhœa, and with some success. The headache seemed to me to be caused by some disorder of the stomach; and under treatment this distressing symptom, or complication, became less frequent. She also enjoyed an interval of three months of freedom from insomnia, and gained several pounds in weight. The insomnia again returned, however, and was as troublesome as before. The treatment consisted in tonics and galvanism. Sometimes for a few weeks the condition of the fingers would seem to indicate recovery, but the results of the six months of my treatment were, upon the whole, indifferent.

PERSISTENT VOMITING AFTER LABOR ARRESTED BY TINCTURE OF IODINE.

By W. T. DODGE, M.D.,

MARLETTE, MICH.

As a supplement to the article by Dr. Eliot in The Medical Record of September 24, 1887, I desire to report the following case:

Mrs. M——, primipara, small, closely built, was taken in labor the evening of November 6, 1887. I found the head presenting in the L. O. P. position. Labor progressed slowly, the occiput finally rotating into the hollow of the sacrum.

I administered an anæsthetic, applied the forceps, and after much difficulty succeeded in delivering the child—a girl, weighing twelve and one-half pounds. The child was asphyxiated, but artificial respiration restored it in ten minutes. The pregnancy had been normal, excepting a tendency to vomiting throughout its entire duration. The patient was much exhausted at the completion of the labor, but the uterus contracted well. Antiseptic precautions were at once adopted. The labor was followed by atony of the bladder, and I very improperly yielded to her solicitation for chloroform-anæsthesia during catheterization. She was in a most weak and nervous condition, and the suggestion of catheterization without chloroform produced so much excitement, followed by partial collapse, that I yielded to her request; the more readily, as she appeared to bear the anæsthetic very nicely. During the first two days she retained a small quantity of light food, but on the third day her stomach rejected everything. I then refused to give more chloroform, and administered all the usual remedies for allaying vomiting, without avail. During the next two days lactopeptine, dilute hydrocyanic acid, carbolic acid, sublimate nitrate of bismuth, lime-water, etc., were each given a faithful trial. Then all attempts at nourishment by the stomach were discontinued, and nutritive enemata were given every two hours, combined with hypodermic injections of brandy. Notwithstanding this, the nausea and vomiting continued until the evening of the the fifth day, when the patient was in a critical condition. Her pulse was 130; temperature, 101° F.; symptoms of impending collapse were apparent. The uterus was firmly contracted, abdomen free from tenderness, and the lochia normal; so I could not diagnose septicæmia. At this juncture I recollected having recently seen an article in The Medical Record on vomiting during labor. I looked over the files, and found the article by Dr. Eliot, previously alluded to, recommending tincture of iodine. I repaired to the bedside of my patient; found her retching and vomiting, and completely discouraged. I gave her five drops of the tincture of iodine in a tablespoonful of sweetened water. Two hours later I visited her again, when she looked up with a better expression than she had shown since her labor, and exclaimed, "I am hungry." I directed the nurse to give her some milk and lime-water, which she retained. During the night she twice experienced slight nausea, which was immediately relieved by tincture of iodine. She has not vomited, in fact, since the administration of the first dose, and is now making a rapid recovery.

AN UNDESCRIBED ARTERIAL MURMUR.

Dr. Samuel A. Fisk, of Denver, Col., referring to the article on this subject by Dr. Seelye, says that he has been studying this murmur for two years past: "As I find it, it is heard, as the doctor says, more usually on the left side. It is loudest in the infra-clavicular space, at a point just below the junction of the middle and outer third of the clavicle. It is most pronounced on deep inspiration, is independent of any heart-sound, and is found in full-blooded, healthy people, when there is no evidence of anæmia. I find it occasionally on the right side of the chest, but rarely, as compared with the left. It is synchronous with the carotid pulse, and while it is most pronounced on a deep inspiration I have frequently heard it during ordinary inspiration. I cannot agree with the doctor, however, in his assertion that 'it is probably of more frequent occurrence in those with inelastic chest-walls, and with more or less condensation or lack of expansive power in the upper part of the lungs.' One of the earliest cases in which I observed it was a strong woman, with an unusual expansive power of the chest, whose lungs and heart were perfectly sound. In her case the murmur was very pronounced, and especially accentuated on deep inspiration. Moreover, the persons in whom I have made most of my observations, and in whom I have most generally found this murmur, have been employés of the Union Pacific Railway—stout, able-bodied men, of large chest-capacity. Still further, in examining a large number of phthisical patients who come to Colorado on account of some consolidation of the left apex, in whom there is a limited chest-capacity, and a consolidation to transmit sounds easily, in no one of them all do I recall having heard this murmur. There is one possible exception. Some two years ago I saw a young man who had extensive consolidation of the left upper lobe. In him there was a murmur, coming a trifle later than the second heart-sound, to be heard over the upper portion of the left side anteriorly, with its maximum intensity about over the second rib in the mammary line. But in this case the *bruit* was decided and clear between the scapulæ; whereas I have never heard the murmur described by Dr. Seelye transmitted to the back. The murmur, in the case cited, led us to strongly suspect an aneurism; but it disappeared as the lung cleared up, and vanished with a recovery from the lung difficulty. I have been greatly interested in this murmur, and in Dr. Seelye's explanation of its causa-

tion. I have thought myself that it might be due to a compression of the artery between a fully expanded lung and the chest-wall. But if that be so, it should be heard as distinctly and as frequently on the right as on the left side, which it is not. May it not be caused by the friction of the blood upon itself, or upon the arteries, produced by an intensified blood-current striking the V where the left carotid and left subclavian arise from the aorta, causing, as it were, an eddying of the blood? Whatever the causation, the murmur is of interest, and has been correctly and vividly portrayed by Dr. Seelye."

Progress of Medical Science.

What are the Chief Factors which Determine the Differences in the Form of the Male and Female Pelves?—In a paper having this title, read recently before the London Obstetrical Society (*The Lancet*, October 15, 1887), Dr. Arburthnot Lane criticised the supposition that many, if not all, of the differences which exist in the form of the male and female pelves are due to the force exerted by the femora and sacrum upon the innominate bones. He considered that the conditions of the thorax and pelvis are exactly analogous in the two sexes, and described in detail the manner in which the female thorax differs as a whole and in its constituent parts from the male thorax. He thought that the factor which determines the altered form of the female thorax from the male thorax (which he regarded as the original type) is the additional function performed by the former—namely, that of accommodating the fœtus during the later months of pregnancy. In the case of the pelvis, that of the female performs one function in addition to those performed by the male pelvis. That additional function is the support and transmission of the fœtus, and he regarded this as the sole factor which determines the variations in form in the two sexes. He thought that there was a fallacy in arguing from the manner in which certain forces produce changes in the pelves of diseased female subjects during the lifetime of a single individual, that the same forces acting upon a healthy female subject determine this peculiarity in the form of the pelvis, and that, should these forces be absent, the characteristic peculiarities do not result. He attempted to prove this point by applying the same argument to the analogous condition of the female thorax. He discussed the two most common variations in the form of the male pelvis and their probable cause, and showed that these variations do not occur in the female subject. The pressure exerted by the fœtus, represented as a developmental factor, is the cause, he considered, which prevents the occurrence of such variations in the female subject. He then alluded to pressure-changes due to carrying loads upon or in front of the trunk, and from premises gathered from these several points came to the conclusion that the sole determining factor of the variations in the form of the male and female pelves is, as in the case of the thorax, the force or pressure exerted by the fœtus. In the discussion which followed the reading of this paper, Dr. Herman agreed with Mr. Lane in holding that the form of the pelvis was due to inheritance—*i.e.*, to influences acting on many generations of ancestors—more than to forces acting during the life of an individual. But he thought the way in which the shape of the pelvis was modified in transmission through many generations was mainly this—that women with well-shaped pelves were able to bear large, strong children, likely to survive and to inherit and transmit that type of pelvis; while women with small pelves produce either stillborn children, or small, weak children, not so likely to survive, and so a stock with small pelves tended to become few.

Gouty Diabetes.—Writing on this subject to *The Lancet*, Dr. Grenville says that persons affected with this malady are generally of large frame, with little stability or power, full-sized but flabby muscles, and a tendency to the accumulation of fat. They are great—or intermittingly great—eaters, and energetic or impulsive, but weak and easily exhausted. The skin is pale, and they suffer from coldness of the extremities. They sleep badly at night, and worry in their wakefulness; while by day they are drowsy, and when falling asleep breathe heavily, or, if not roused, sink into a state verging on coma, with puffing, sighing, or labored respiration. They are commonly subject to attacks of vertigo, in which surrounding objects seem to race from left to right; and not seldom they have weak hearts with rhythmically irregular pulses, and perhaps a short mitral systolic murmur, which is not constant, but more likely to be heard when the heart is acting languidly than when it has been recently stimulated by exercise. The characteristic phenomena are: (1) Very great variability in the quantity, color, and density of the urine passed in twenty-four hours, and the want of relation between the bulk of the fluid consumed and that excreted; (2) sugar is present when the urine is small in quantity rather than when it is abundant; (3) the acidity is abnormally low in proportion to the percentage of urea; (4) there is generally much uric acid (Haycraft's test) when the sugar is absent, and less than the average proportion of health when sugar is present; (5) albumen is often found soon after a meal, either with the sugar or during a free elimination of uric acid, and when there is no albumen the phosphates are generally in excess; (6) the liver is enlarged *vertically*, and the bowels are constipated, with occasional attacks of diarrhœa, the stools being pale when scanty, and bilious when profuse. Hemorrhoids are usually present and troublesome in these cases, and when they do not bleed they often attain great size. Not infrequently there is also a prostatic gleet. In the management of cases of this class many difficulties have to be encountered, and they are far from easy to overcome. Meanwhile one thing is certain, namely, that, dieted as it is the fashion to diet patients suffering either from gout or diabetes, and treated on conventional principles either at home or at the continental spas, the subjects of gouty diabetes do not do well. They may be for the moment relieved, but they quickly relapse, and, on the whole, go from bad to worse steadily. It is with a view to plead for a more generous regimen and tonic treatment that Dr. Grenville writes. Wisely, but liberally fed, with meat in such quantities as the stomach will take, *ordinary* bread and vegetables—in short, a full mixed diet—dry champagne, which contains a minimum of alcohol and a large proportion of ether, and well-matured port wine, in appropriate and measured quantities (the effect being carefully watched), they do well. The albumen and sugar disappear; the quantity of urine excreted becomes normal and relatively regular. The pulse gains strength and rhythm, and the condition throughout improves, under some modification of the following treatment: Ferri lactatis, gr. 10; acidi lactici, ℥. 15; quiniæ puræ, gr. 1; extracti convallariæ fluidi (*e floribus*), ℥. 10; aquæ ad oz. ½; every sixth hour, or in bad cases every fourth, or even third, hour. Should there be constipation, add five or ten minims of the fluid extract of cascara sagrada (U. S.); or diarrhœa, or excessive diaphoresis, ten minims of tincturæ cotonis.

Micro-organisms in Inherited Syphilis.—Doutrelpont says that early last year Kassowitz and Hochsinger reported the detection in the organs of five cases of hereditary syphilis of streptococci, which were contained within capillaries or their vicinity. These cocci differed from others in that they were not associated with suppuration. The authors refrained, however, from stating their precise significance. Kolisko, who had made numerous preparations from syphilitic infants dying within a day or two after birth, had failed to find streptococci, except in one case of furunculosis, and this he attributed to infection by the streptococci pyogenes. Again, Chotzen, in Neisser's clinic at Breslau, had discovered strepto-

cocci occasionally in the bones, skin, liver, and intestinal mucosa of subjects of hereditary syphilis. But he looked upon their occurrence as accidental, although there is no doubt these particular microbes are different from those of erysipelas and suppuration. Chotzen suggests that the cases in which they occur are instances of mixed infection, and that a streptococcus-septicæmia may be the cause of death in many cases of hereditary syphilis. The ulcerated surfaces of the mucous membranes might be the entrance of the streptococci. Doutrelpont says that in pursuing his researches upon bacilli in syphilis he met with streptococci in papules removed from an infant that died fourteen days after birth. No lesion of bones or internal organs was found in this case. The histological examination of the affected skin showed the horny layer of the epidermis over the papules to be raised up, and between this and the rete mucosum were masses of streptococci and staphylococci, especially abundant in the hair-follicles and ducts of the sebaceous glands. The cutaneous papillæ were infiltrated with small cells, especially around the vessels, and streptococci were met with here also. The blood-vessels were for the most part free from cocci, but in a few which contained blood streptococci were seen between the corpuscles. On the other hand, the lymphatic channels were blocked with the micro-organisms, some of which were even detected in the subcutaneous tissue around the sweat-glands and between muscular fibres. By using special double-staining methods, the author was enabled to display in the same specimens the bacilli which have been described as characteristic of syphilis, although they occurred but sparsely. He believes that the streptococci have no relation to the syphilitic process, for he has never met with them in all his previous and numerous examinations of syphilitic products. He inclines to Chotzen's view, that their presence is due to a septic infection, which the cutaneous and mucous lesions of syphilis render possible.—*Centralblatt für Bakteriologie.*

Ptomaïnes as Causes of Error in Toxicological Research.—At a meeting of the Académie de Médecine M. Brouardel read a communication by Ogier and Minorici on ptomaïnes as causes of error in toxicological research, of which the following is a *résumé* (*The London Medical Record*): 1. The liver and kidneys furnish residues that have in general the same reactions. 2. The most abundant residuum is furnished by amylic alcohol (alkaline solution), and by benzine and chloroform (acid solution). Petroleum (hydride of hexyl) takes nothing, or next to nothing, away from alkaline solutions. 3. In one case only (a fœtus of seven to eight months, presenting no signs of putrefaction) the residuum showed no alkaloid reaction. In all the others more or less of basic substances were obtained, precipitated by general reagents; by far the most sensitive of these reagents being iodide of potassium iodized. The residues are considerable from viscera in which putrefaction has hardly commenced (bodies of two to four days in summer); more abundant from viscera in active putrefaction (bodies of eight to twenty days); beyond a certain limit of putrefaction (bodies exhumed after two years or more) the quantity of ptomaïnes ostensibly diminishes. 4. The tabular results of these experiments show the amount of confidence that may be reposed in different colored reactions in the search for vegetable toxic bases, and the influence of ptomaïnes on the reaction. For example, perchloride of iron has never given any coloration; it is therefore a good reagent for morphine. Alcoholic potash, after oxidation by nitric acid, never gave a violet reaction comparable to that of atropine. Nitric acid alone often gives yellow or orange coloration much less intense than that obtained with brucine, but capable of being confounded with the tint that would be given by a trace of morphine. The use of reagents containing a large excess of sulphuric acid (molybdate, vanadate, selenite, etc.) is rendered very uncertain by the presence of ptomaïnes; for mixed tints are obtained, reddish or inclining to violet, and very often identical with those given by sulphuric acid alone. With bichromate of potash and sulphuric acid, on one occasion only, a violet tint was obtained similar to that given by a trace of strychnine; with alcoholized sulphuric acid and perchloride of iron certain residues gave greenish tints, capable of being confounded with those of digitaline under similar circumstances. Without giving undue importance to these causes of error, it is necessary to take them into consideration. The tints due to the presence of ptomaïnes are never as decided and as evident as similar tints produced by vegetable bases. Besides, one colored reaction does not suffice for a decided conclusion; it is necessary to consider the *ensemble* of the chemical and physiological facts, so that, in fact, the chances of error are very slight.

Hæmatology in the New Born.—Hofmeier had found that the size of the red blood-corpuscles was very variable; that their form was more spherical than in adults; that they showed no tendency to run into rouleaux; that the white corpuscles are often in greater proportion than usual; that the white corpuscles tend to accumulate in rouleaux, and that they are viscid, deliquescent, and easily destroyed. Silbermann confirms Hofmeier, and also shows in addition that the blood of the new-born contains *shadows*, which are certain delicate pale rings forming the stroma of red blood-disks, the coloring matter having been removed. These bodies, first discovered by Ponfick, are found to be more abundant the more disturbed is the child's general condition during the first few days of life. Hæmoglobinæmia induced by this general disturbance does not always lead to hæmoglobinuria; but if it occurs, then, according to Schmidt and his disciples, the circulating blood will contain a relatively large quantity of fibrin ferment, red and white corpuscles having contributed to this result. Silbermann concludes, from experiments on frogs, dogs, and puppies giving results in the blood identical with those deviations met with during the first few days of life in the blood, urine, and liver of infants, that there is a free destruction of red corpuscles, resulting in the liberation of free hæmoglobin. Venous stasis and hyperæmia were found, and attributed to this consequent increase in the fibrin ferment, resulting from excessive destruction of the red and white blood-corpuscles. So it seems that the condition of the blood in the newly-born predisposes to disease, and, in the presence of such conditions as asphyxia, omphalitis, syphilis, gastric and intestinal catarrh, and erysipelas, is likely to be of grave importance. It is supposed that the liver would convert the extruded hæmoglobin into bilirubin, and this is perhaps one of the natural functions of the liver, which, for aught we know to the contrary, may also aid in the destruction of the red blood-disks as well as in the manufacture of bile. It is possible that this destruction and manufacture are one and the same process. The conclusions of Silbermann are: The blood of the newly-born shows evidences of imperfect stability in the variation in size of the corpuscles, in the presence of *shadows*, and in being rich in fibrin ferment. These results may be due to liberation of the hæmoglobin, and they may predispose to disease, since all morbid processes involving great destruction of albumen in the circulation are probably very dangerous to life.—*Archives of Pædiatrics.*

The Consumption of Beer in France.—The quantity of beer consumed in France varies remarkably in the different cities. Thus in Nantes only 4 litres a year for each inhabitant are drunk; in Paris, 12 litres; in Havre, 22; in Nancy, 48; in Amiens, 100; in Saint-Quentin, 234; and in Lille, 301. But France is still far behind its hated rival, Germany, in this respect. In Munich, the amount of beer consumed reaches the very respectable figure of 400 litres a year for every man, woman, and child in the city.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 24, 1887.

AN INTESTINAL ANTISEPTIC.

CAREFUL bacteriological studies have shown that none of the drugs ordinarily used internally as antiseptics have much, if any, potency, so far as the fermentative changes in the intestine are concerned. Calomel, bismuth, salicylic acid, naphthalin, carbolic acid, all diminish the number of micro-organisms in the fæces but slightly, perhaps one-fourth or one-third at the most. Given in large enough doses to be really effective germicides, they are all dangerous to life.

To secure a real intestinal antiseptic we must find a drug but very slightly soluble, nor readily decomposable, non-irritating, of powerful disinfectant property, and, comparatively innocuous to life, even when it does reach the circulating fluids of the body. Rossbach thought that in naphthalin such a substance had been found, but in this, later experience shows that he was mistaken.

In a recent communication to the Académie des Sciences, M. Bouchard claims to have found a substance which does fill all these requirements, viz., naphthol. Naphthol is not a new drug. It has been used by dermatologists for six or seven years, and by surgeons for a somewhat shorter time. The preparation usually employed is the beta-naphthol, and this is what Bouchard uses. It is obtained from tar, and is a substance soluble in alcohol, but not in pure water.

Bouchard first made a series of experiments to determine its germicidal power. With regard to pyogenic micro-organisms, he found that a solution of 0.40 per 1,000, or 0.04 per cent., was sufficient to prevent their development. This, he states, is one-sixteenth the strength of mercuric biniodide, and five times the strength of carbolic acid.

But though less powerful than mercury as an antiseptic, it has the advantage of being comparatively harmless to the human body. As the result of tests made, Bouchard states that the toxic dose of naphthol for a man weighing one hundred and thirty pounds is 250 grammes, or about half a pound. On the other hand, a daily dosage of 2.50 grammes, or less than forty grains, is sufficient to produce intestinal antisepsis. Toxic, not lethal, effects have only been produced when the naphthol was ingested in doses of about twenty-six grammes. The phenomena are those of albuminuria, spasmodic muscular contractions, salivation, and coma. Hæmoglobinuria has not been observed.

Bouchard gives the following interesting tabular statement of the comparative antiseptic power, toxicity, and dosage of several different substances:

	Antiseptic dose.	Toxic dose.	Daily toxic dose.
Iodoform	1.27 per 1,000.	0.50 gramme.	0.05 gramme.
Iodol	2.75 " "	2.17 grammes.	1.24 "
Naphthalin	1.51 " "	3.40 "	1.60 "
Beta naphthol.. ...	0.40 " "	3.80 "	1.10 "

NAPHTHALIN AND CALOMEL IN TYPHOID FEVER.

THERE has been a large amount of clinical evidence tending to show that calomel and naphthalin are efficient drugs in typhoid fever, lessening its severity and even at times aborting it. Dr. Fürbringer (*Deutsche Med. Wochen.*, 1887, Nos. 11 to 13) has been investigating this question both clinically and from a bacteriological standpoint, with results somewhat disappointing to hopeful therapeutists. Naphthalin was first tried in one hundred consecutive cases of typhoid fever. It was given in doses of 3 to 5 grammes daily, according to the Rossbach-Götze formula. Mild baths were also employed, but no other special remedies. Dr. Fürbringer concludes that the drug had no influence in shortening or aborting the disease, or in preventing complications or relapse. Still more positive were his bacteriological studies. He found that the fæces of patients not taking naphthalin contained 112,000 micro-organisms per milligramme, while during the use of naphthalin the number was only reduced to 90,000. Furthermore, the naphthalin did not kill the typhoid bacilli, and these could be cultivated from the stools without any difficulty.

Calomel given in good doses at the beginning of the disease had a striking action upon the temperature, lowering it for some time. Fürbringer seems to think that this result does not occur in other fevers, and infers that it is in a measure a specific action. There is, however, plenty of evidence to show that calomel does act similarly in other febrile diseases, such, for example, as pneumonia. In the calomel stool the number of micro-organisms is about three-fourths that in the ordinary stools, or 81,000 per milligramme.

The typhoid bacilli are not killed, and such action as calomel possesses cannot be due, therefore, to any anti-parasitic process. Fürbringer thinks that the drug does possess a certain amount of specific action, but that, practically, the calomel treatment of typhoid fever does not materially influence the course or mortality of the disease.

ON THE PATHOLOGY OF TRISMUS AND TETANUS NEONATORUM.

THE cause of tetanus in the new-born has long been a subject of dispute. The disease has been ascribed to pressure from inward displacement of the occipital or parietal bones, to phlebitis of the umbilical vein, to uræmia, rheumatic influences, and to umbilical injuries. The fact that in severing the umbilical cord a traumatic lesion is produced, has led many to insist on this being the point of origin of the disease; yet cases of inflammation of the umbilical vein and of unhealthy umbilical granulations have been observed without tetanus fol-

lowing. The tendency of modern pathological investigations is to show that tetanus is a specific infectious disease due to some micro-organism. The experiments of Rosenbach, Nicolayer, and Carle and Rattone give weight to this view, although it is not yet placed on an established basis.

It would be natural to infer that the tetanus and trismus of the new-born had a similar pathogeny to that occurring in adults. In the *Berlin. Klinischer Wochensch.*, No. 30, 1887, Dr. Beumer announced that he had been able to communicate tetanus to mice and guinea-pigs by inoculating them with tissue taken from the umbilicus of an infant who had died from the disease in question. Beumer's conclusion was that tetanus or trismus neonatorum is not a reflex neurosis of unknown origin, but, like traumautic tetanus, is an infectious disease. Dr. E. Peiper, of Greifswalde, in a communication to the *Centralblatt für Medicin* of October 15th, corroborates completely the experiments of Beumer. In an infant suffering from typical trismus, parts of the navel were carefully removed with sterilized instruments, and with the usual technical precautions. Inoculations were made in six mice. Three of the animals began to suffer typical symptoms of tetanus in twenty-four hours, and died in two days. The three other animals developed the disease less perfectly, but eventually died of it. Guinea-pigs were then inoculated with bits of tissue from the neighborhood of the wound in the dead mice. Five days later these animals developed tetanus. The evidence thus furnished appears to show that tetanus neonatorum is an infectious disorder, of microbic origin, and identical with ordinary traumatic tetanus. Inoculation of the umbilical wound with the specific virus is the direct cause.

It is most likely that this view will turn out to be the correct one for most cases. Tetanic and trismic symptoms in infants may, however, no doubt be sometimes produced by pressure or reflex irritation. Marion Sim's view regarding pressure as a cause has always rested on incomplete evidence. But one may admit that displacement of cranial bones is sometimes a factor, and in practice the skull should always be carefully examined. At the same time the rational treatment for trismus and tetanus neonatorum is the preventive one, and this in the light of recent discoveries seems to consist in an antiseptic treatment of the umbilical cord and the navel.

THE CONDITION OF THE CROWN PRINCE.

(Cablegram from Sir Morell Mackenzie to THE MEDICAL RECORD.)

SIR MORELL MACKENZIE, in a cablegram to THE MEDICAL RECORD, takes a hopeful view of the present condition of the Crown Prince of Germany. "A new growth of small size has appeared on the left ventricular band, and gives the appearance of a false excrescence. The October growth, which gave rise to so many distressing symptoms, is now much smaller, and the ulceration on its surface has cicatrized. There has been no recurrence of the original growth which was removed from the posterior portion of the left vocal chord last summer. The infiltrated glandular swellings have disappeared."

The disease is evidently, for the present, in a quiescent condition. The new growth, which is above the site of the original one, is doubtless of the same character as others which have preceded it. As far as can be judged from the facts before us, the disease is destined, barring accidental complications, to progress slowly. A specially hopeful sign in that direction is the non-recurrence of the first tumor removed. From all appearances the progress of the disease is arrested from that point, and gives encouragement for persistence in the present line of treatment.

As we have supposed, the October growth, although really an extension of the disease, gave rise to local symptoms which were out of all proportion to its special malignancy. The associated conditions of inflammatory infiltration of the glands of the throat and subsequent suppuration of the parts in the neighborhood were due to accidental and transitory complications. Hence we now learn that after the discharge of pus the swellings have disappeared, and the growth itself has apparently diminished in size. The disease still has a clinical history of malignancy, although, by the present judiciously conservative treatment of Sir Morell Mackenzie, it is destined to be kept in abeyance for a very considerable period.

News of the Week.

DR. V. P. GIBNEY, Professor of Orthopedic Surgery in the New York Polyclinic, has been made Surgeon-in-chief of the Hospital for the Ruptured and Crippled.

THE SLOANE MATERNITY HOSPITAL AND THE VANDERBILT CLINIC.—The exercises on the occasion of the opening of the Sloane Maternity Hospital and of the Vanderbilt Clinic will take place in the lower lecture-room of the College Building, 437 West Fifty-ninth Street, on Thursday, December 29, 1887, at 3 P.M. The address will be delivered by Professor T. Gaillard Thomas, M.D. The profession are invited to be present. Seats will be reserved for ladies.

BRAIN SURGERY.—We learn that in the case of cerebral tumor which was removed lately by Dr. Weir, at the New York Hospital, the patient has recovered sufficiently to go to his home in Bridgeport, Conn. The tumor had been correctly located by Dr. Seguin in the white substance below the arm and face centres, and was found in this locality, one inch below the surface. Full particulars will appear later in our columns. Since this operation was performed Dr. Keen, of Philadelphia, has removed a fibroma, weighing over three ounces, from the brain. Dr. Abbe, of this city, last week, by a similar operation, evacuated a cerebral cystic tumor.

ANOTHER DISCOVERER of the cancer-bacillus is announced in the person of Dr. Schill, of Dresden. He described his bacillus at a recent meeting of the Berlin Society for Internal Medicine. It resembles that of Scheuerlen. The former gentleman's experiments are described as follows by a correspondent of the *British Medical Journal*. Dr. Schill made experiments with about forty specimens of cancer of the breast; from every specimen he inoculated twenty culture-tubes. Of these eight hundred inoculations, four hundred had been fruitful. He obtained the cancer-juice aseptically, and

cultivated from it a micro-organism which proved to be a spore forming bacillus. Cultivations were made upon exudation taken by puncture from a case of pleurisy with effusion, put in the sterilizer for five days, and coagulated on the sixth day; cultivations made upon blood-serum, agar-agar, peptone, gelatine, or potato were equally successful. The growth was very luxuriant, taking place in the following manner: The bacilli were first found in the growth; then in from twelve to twenty-four hours spores made their appearance, and covered the entire surface. In microscopical preparations of the cancer-juice itself the same spores were found, often in much smaller number than the bacillus, while it has never yet been seen in sections. The microbe forms upon the surface of the culture materials a thin film, which is either transparent or of a yellowish brown. The bacillus can be stained by all the methods in use (very easily by Gram's method); the spores are stained with difficulty, and only by Professor Ehrlich's process for staining the tubercle bacillus. Both the bacillus and its spores have spontaneous movements. The spores are to be found mostly outside the cells, rarely single, generally in clusters, as though the cells were sprinkled with them. Experiments were made on six female dogs; the cultivations were injected into the mammary gland, but no conclusive results have been obtained. A soft swelling, not distinctly circumscribed, formed at first, and then diminished; it became compact and circumscribed, showing under the microscope a decidedly epithelial character, much related to cancroid. This bacillus Scheuerlen believes to be certainly the cause of cancer. In the discussion upon Scheuerlen's report, Professor A. Fränckel, one of the first bacteriologists of Germany, objected to the method by which these experiments had been conducted, saying that secondary infections might easily have taken place, such as frequently occur. Neither did the quick growth of the bacillus answer to the slow growth of cancer, as hitherto found in all clinical experience.

Progress of Cremation.—Europe has twenty-two crematories, situated in London, Paris, Rome, Brussels, Gotha, Dresden, Florence, Copenhagen, Milan, and other cities. Ten of these have been erected within the past year. There have been 600 incinerations in Germany and 800 in Italy. In the United States there are twenty-one cremation societies and seven crematories; the latter are located at Fresh Pond, L. I.; Washington, Pa.; Lancaster, Buffalo, Pittsburg, Cincinnati, and Los Angeles. Crematories are in course of erection in Philadelphia, Baltimore, St. Louis, Detroit, San Francisco, and Davenport. At the Fresh Pond crematory there have been about one hundred and forty-seven applications for incineration in two years.

"Chancre Medicine" is the name given by the Indians of Arizona to iodoform. These sufferers from excess of civilization call for the drug as regularly as for rations and blankets.

In Bright's Disease without Albuminuria there is a lessened excretion of urea and other toxic elements. A good way to determine this lessened toxicity is to note the result of the injection of a certain quantity in the veins of some animal, as the hare. With normal urine, it is necessary to inject fifty grammes for every kilogramme of the animal's weight in order to kill the animal. Thus if the animal be a hare weighing two kilogrammes, the quantity necessary to produce death will be one hundred grammes of urine. In the pathological state, however, where from atrophy of the glomerules, or other cause, impeding or suppressing their function, the waste matters are much less than in the normal state, it takes a much larger quantity of urine, when injected into the veins of the animal, to kill it; one hundred grammes, and even more, per kilogramme, will fail to have a decided toxic action. Sometimes such urine seems to be almost as harmless as water.

Buffalo, N. Y., is a large city with some two hundred regular physicians. But these exponents of a presumedly learned profession refuse to support a medical library whose annual expenditures are only one hundred and fifty dollars a year. The Buffalo Medical Library Association is about to collapse, after five years' existence, from want of sufficient funds. Yet Buffalo has two medical colleges, two medical journals, and asks to be regarded as something of a medical centre.

Refusing to Treat Wealthy Patients in a Charity Hospital.—According to the *Medical Standard*, Dr. Norman Bridge, of Chicago, has been attacked with great venom by the Chicago *Tribune* because of his refusing to treat wealthy patients in the County Hospital. Dr. Bridge's action is thought by our contemporary to redound greatly to his credit, and so it does if the facts given by the *Standard* are correct.

Criminal Assault on Chloroformed Women.—The Texas Supreme Court has recently decided that criminal assault committed while the female is under the influence of chloroform does not constitute rape. This is in opposition to many English and most American decisions, although the same view, says the *Medical Standard*, is held by some English judges. Medical opinion will, we believe, not uphold the justice of this view. It is an established fact that persons while asleep can sometimes be chloroformed, and in such cases criminal assault could be committed with impunity.

The Annual Report of the Marine Hospital Service for 1886–87, shows that 45,317 patients were treated during the year. The expenses of the service were $461,336.17. The report contains a number of records of cases, medical and surgical.

An Historical Correction.—According to Mr. L. H. Petit it was a Frenchman named Méry who first discovered and described the bulbo-urethral glands. This he did in 1684; Cowper described them in 1699. They should be called, therefore, the glands of Méry, not the glands of Cowper.

Buckwheat Rash.—Dr. Wm. B. Atkinson writes to the *Philadelphia Medical Times* that this is the time for eating buckwheat cakes, and desires to learn whether the prevalent opinion that eating this article of food tends to produce a rash, more especially in young children, is correct. We trust that Dr. Atkinson will be successful in his modest attempt at collective investigation. For our part, we believe that the consumption of buckwheat cakes by young children is rash, whether such dietetic indulgence produces it or not.

One of the Smaller Hospitals of this city, the Presbyterian, has withdrawn from the Hospital Saturday and Sunday Association. Judging from comments in the daily press, this action adds to the unsavory reputation of the hospital as a small sectarian institution.

Signing Death-certificates.—The San Francisco Board of Supervisors have issued an order which excites surprise and comment; simply because it is a patently needed measure, that should have been taken long ago. This order requires that permits for burials shall only be granted upon presentation of a death-certificate signed by a legally qualified physician.

Physicians in Congress.—Among the 325 members of the House of Representatives there are 6 physicians, 2 druggists, 3 clergymen, and 216 lawyers. One hundred and seventy-eight are college-bred men. Twenty-seven are foreign born.

Trauma as an Antipyretic.—Dr. Tuke relates the history of a man who was cured of acute rheumatism by a railroad collision, and of a lady who was cured of the measles by hearing that her husband was well. The *Indiana Medical Journal* says that recently, while in the second week of typhoid fever, a patient in the Indianapolis City Hospital jumped from a third-story window, falling a distance of forty feet. He suffered but little injury from the fall, but it seems to have knocked the fever "higher'n a kite." At any rate, the temperature rapidly subsided, did not return, and the patient made a speedy recovery.

Cocaine in Sea-sickness.—Dr. Hartz communicated to the Société de Biologie, at its meeting of October 29th last, some observations on the administration of cocaine in sea-sickness. He found that it was an excellent remedy, in doses (which should not be exceeded) of ten centigrammes, in a ten per cent. solution. He gives twenty drops pure, which gives instant relief. He has also had good results with subcutaneous injections of cocaine. The injection is scarcely felt, and is never followed by any unpleasant effects. It should be performed in preference in the abdominal wall.—*British Medical Journal.*

Guacol, obtained from creasote, is recommended by Sabli as a substitute for the latter drug, in doses of one-fourth to one-half a drop. Creasote, he says, is often impure, and guacol is the essential remedial agent in it.

A Congress for the Study of Tuberculosis in Men and Animals will be held at Paris, July 25 to 31, 1888. The Committee of Organization contain such men as Chauveau, Villemin, Cornil, Grancher, Lannelongue, and Verneuil. The subjects to be discussed are: 1. The dangers from using the meat and milk of tuberculous animals. 2. The susceptibility of the human race and of different animal species to tuberculosis. 3. Modes of introduction and propagation of virus in the economy. 4. The early diagnosis of tuberculosis in men and animals. The Secretary-General of the Congress is Dr. Petit.

A Course in the Microscopical Anatomy and Pathology of the Nervous System is to be opened at the New York Post-Graduate School, under the direction of Dr. C. L. Dana and Dr. William H. Porter.

The Following Curious Letter has been received by Sir Morell Mackenzie: "Morell, fy! thou curmudgeon, thou wilt be a doctor, thou art a mean bungler! Be by no means proud of the confidence of our good crown prince; it is now only pity with thee, thou dunce, thou blockhead, thou ass! Therefore, thou huddler, be on guard, when thou travellest through Germany again, thou knave!—One of the German Secret Union."

Rival London Laryngologists.—We are not, perhaps, quite so bad after all here in America, if one may judge from the following criticism of some of the laryngological lights of Europe. The *Medical Press* says: "There is evidence of a firm determination on the part of the rival laryngologists of London to make hay while the sun shines. In speech and in print, in the lay as well as in the medical journals, this industrious and indomitable fraternity (a divided family!) avail themselves of every opportunity of speculating on the etiology, course, and treatment of 'benign versus malignant neoplasm of the larynx.' It may be said, indeed, of the wart in the Crown Prince's throat that 'thereby hangs a tale,' and what a tale!—a tale of jealousy, heart-burning, and disappointment. So intense have these feelings become, that from London to Vienna the votaries of the science have, with one or two illustrious exceptions, thrown off the mask of common courtesy and professional etiquette, and have striven with each other to obtain the notoriety which is so dear to them." There are some very honorable exceptions, it should be remembered, to the class referred to by our contemporary.

The Local Application of Vaseline to the nasal cavities, which is a somewhat popular measure just now, receives this comment from the *Southwestern Medical Gazette*: "The only argument in its favor is one which is similar to that of an old negro who declared that he did love to stump his toe, because it felt so good when it quit hurting. So with the application of vaseline to a catarrhal nasal membrane—it feels good after it has been put into the nose."

The Solubility of Saccharin.—Some disappointment seems to have been experienced in various quarters as to the sweetening qualities of saccharin. This is probably due to its insolubility, under ordinary circumstances, in water and watery solutions, to overcome which it must be mixed with a small quantity of a suitable alkali, such as bicarbonate of sodium. For practical purposes, it is probably best to obtain saccharin, duly mixed with the soda, in the form of tablets, which are convenient for dosage and readily soluble. Half a grain in this form will generally be found sufficient to sweeten an ordinary breakfast-cup of fluid.

The Doctor as a Substitute for Prisons.—Prince Krapotkine recently delivered a lecture in Paris on "The Moral Influence of Prisons." He argued that prisons were of no use as safeguards to society; that criminals were persons who were suffering from some disease of the brain, heart, or stomach. The only way to deal with such classes was to put them under medical care in order to cure their physical disease. Krapotkine's views contain a germ of truth. A considerable proportion of criminals have congenital brain-defects, and many more have bodily deformities, phthisis, syphilis, and other diseases.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 15, 1887.

A. Jacobi, M.D., President, in the Chair.

BEQUESTS TO THE ACADEMY.

Dr. James Knight bequeathed to the Academy a bass-relief of Valentine Mott, and an oil painting of Benjamin Rush, which were presented, and their receipt acknowledged by the President.

The President appointed, as tellers for the annual meeting, Drs. Reginald H. Sayre, E. F. Brush, and E. V. Agramonte.

After the reports of some of the Sections had been read, Dr. T. H. Burchard read a paper on

THE MODERN OPERATION IN STRANGULATED HERNIA,

in which he pointed out the gratifying contrast between it and the old method of treatment. He urged a more general recognition by the profession of the value of time in the early stages of strangulation, and continued the earnest protest against the habit of procrastination, which he believed had done much to sustain the operation.

Modern herniotomy implied the abandonment of certain medical practices, such as had been adopted to produce relaxation of the parts, as it had come to be recognized that spasm, as a cause in strangulated hernia, never exists. Modern herniotomy also restricted taxis to limits which were rational and safe; it also implied early resort to the cutting operation. If taxis did not succeed under anæsthesia within about an hour, preceded by the local application of ice, he resorted to operation, under antiseptic precautions. He had not had occasion to cut earlier than six hours after the strangulation began. The operation implied the free and impartial judgment of the operator as to what should be done with the sac. His plan of treatment was outlined as follows: Allay pain; apply ice-poultices if there was evidence of inflammation, or the tumor was tender; make no attempt at reduction; give a stimulating enema, and then, within a few hours, put the patient under full anæsthesia with chloroform; elevate the lower extremities; apply taxis half an hour or so, and, if not successful, operate. No operation for strangulated hernia could be said to be properly performed without closure of the hernial canal. The method of treating the adhesions and disposing of the sac were then considered, and a flat-grooved director and hernia-knife were exhibited.

Dr. R. F. Weir read a paper on the question,

HOW SHOULD THE SAC BE TREATED IN HERNIOTOMY?

and divided his subject into three parts.

First, Had the rate of mortality been increased by removal of the sac?

Second, How was this additional operation to be done? and,

Third, How reliable was the procedure for effecting a cure?

From statistics including a total of 285 cases treated radically there was a mortality of 15.8 per cent., showing a reduction of nearly twenty-five per cent., due largely to the radical operation. Antiseptics, *per se*, had not materially diminished the rate of mortality.

The mode of procedure he had already described in The Medical Record for March, 1887, which consisted essentially in liberating the hernial contents, properly treating the intestine, etc., then stripping up the sac to the level of the peritoneal cavity and ligating and cutting it off, or adopting either Czerny's or Macewen's method. Whatever method might be adopted, all surgeons were agreed on closing in some way the mouth of the hernial sac. He preferred to use heavy catgut for sutures. His experience led him more and more to the use of a simple bandage for support after the operation. As to the permanent results, they had been favorable in his group of 55 cases; 38 were cured completely for periods ranging from six months (total time under observation) to nine years. Macewen had published similar statistics, and in another group of 138 cases relapses occurred in only 68. In conclusion, the speaker said that while it was a marked improvement in the treatment of hernia, it could not be considered yet as a perfect operation.

Dr. W. B. De Garmo read a brief paper on

IRREDUCIBLE AND INCARCERATED HERNIA.

What he had to say did not relate to strangulated hernia, nor to those cases in which the protruding mass was in an inflammatory condition.

The abandonment of such cases he regarded as entirely unjustifiable, and to sustain that view ten illustrative cases were reported—eight males and two females. The results were seven reductions, two failures, and one was abandoned on account of the diabetic condition of the patient.

His method of converting an irreducible into a reducible hernia was to see that the mass was freely movable in the sac, and then reduce it more by compression than by taxis, by manipulation of the neck of the sac, but without making any pressure backward.

Work the contents free from its connections from the bottom of the sac upward, and gradually carry it up over the external abdominal ring. Nothing but the most gentle manipulation should be practised. If reduction cannot be effected he adjusts a pad, which presses upon the neck of the omental contents and produces atrophy, as a rule, from strong truss-pressure. Besides, the patient wears a strong suspensory support.

Dr. A. G. Gerster made some remarks on

STRANGULATED HERNIA IN CHILDREN,

which occurs only very rarely. He directed attention to that part of the treatment which differed from that generally employed in adults. After attempts at reduction had proved useless, the cutting operation must be performed, and, the operation having been completed, how should the wound be treated? In most of the cases the neck of the sac is not very wide. The first indication to be fulfilled was to add the radical operation to the liberation of the gut. The second question has been stated already, namely, How should the external wound be treated? It had been advocated by Dr. Weir and others that better protection against relapse would be afforded should it be allowed to close by granulation. He did not share in that opinion, however, in adults, but in children he would advocate

OPEN TREATMENT OF THE WOUND,

packing it with iodoform gauze, and treating it as any other open wound would be treated. Dr. Gerster then reported three illustrative cases, in one of which an error in diagnosis was made at first, it being regarded as a case of hydrocele; it was a case of strangulated hernia without symptoms, but the usual symptoms of strangulation followed within twelve hours.

Dr. Dixon Jones said that the open operation, or operation by dissection, for the radical cure of hernia, is now established on so firm a foundation that little need be said in its justification. Judging from his limited experience, which comprises six cases, he thought he was justified in saying that to the practical surgeon, and especially one who was thoroughly imbued with the principles which underlie the antiseptic treatment, the operation was eminently a safe one.

It has been so thoroughly discussed that he wished merely to emphasize certain points referred to by the previous speaker. At the last meeting of the British

Medical Association, the subject of the radical cure of hernia was discussed by no less than ten or twelve surgeons, and he thinks almost as many different operations were advocated. It seemed to him that if the surgeon was perfectly familiar with two or three of them, he would be prepared to meet any difficulty that might arise. The first was that of Macewen, which had been described already; the second was one that he recommended at the last meeting of the Medical Society of the State of New York. It differed from Macewen's only in the manner of treating the sac, which was disposed of as follows: An incision was made in the direction of the inguinal ring until the sac was reached; which was then cleaned and separated, and excised flush with the peritoneum, the edges of which were united with a continuous catgut suture.

He had had the opportunity of witnessing many operations for the radical cure of hernia, and was convinced that Macewen's method was not well understood by a number of surgeons. Mr. Mitchell Banks and several German surgeons had informed him that they did not understand what Macewen meant by his *operation*. It should be remembered that it was not the internal wall of the external hernial opening that was approximated to Poupart's ligament, but the conjoined tendon. He had a model, which was a reproduction of one shown him by Dr. Macewen, and clearly illustrated how the inguinal canal was closed in a valve-like manner. He felt greatly pleased that one of the speakers had practised the method which he had suggested. Dr. Jones also presented Reverdin's needle which he recommended for the purpose of introducing the shoemaker's suture of H. O. Marcy.

Dr. V. P. Gibney entered a mild protest against Dr. Burchard's disapproval of taxis, as he believed that very much could be accomplished by that manipulation, properly performed.

As to strangulated hernia in children, he did not recall a single case in which he had not been able to effect reduction under chloroform; and if the hernia could be reduced it could be cured by a truss, which would relieve us from any operative procedure whatever in children.

Dr. Wylie spoke of ventral hernia after laparotomy, which could be prevented by reuniting the edges of the strong fascia, which was really the tendon of the transversalis muscle. He also mentioned the liability of the scar, after the use of a drainage-tube, to yield, and thus allow a hernia to form.

Dr. Weir had had two cases of fatal strangulated hernia in children. He had also had two other cases in which, by the introduction of the finger into the rectum, he was able to sweep the entire inguinal region, and by the conjoined manipulation succeeded easily in reducing the strangulation.

It was worthy of note that

HERNIA VERY RARELY FOLLOWED OPERATION FOR PERITYPHLITIS.

Dr. Fruitnight asked Dr. Gerster if the symptoms of strangulation usually present in adults were absent in children.

Dr. Gerster answered that the usual symptoms present in adults were also seen in children, though in one of his cases they were absent early; but the general aspect of all the cases was such that serious interruption of circulation had to be assumed.

Dr. De Garmo had seen a large number of cases in children in which the hernia was incarcerated temporarily. He had not met with strangulated hernia in infants. He had never attempted taxis upon the temporarily incarcerated hernia, and those cases did not give rise to symptoms.

Dr. Gerster thought that if the gut was healthy, herniotomy was not dangerous; but in cases where necrosis had taken place, the treatment of the incarcerated or strangulated portion by the older methods, or by the use of a probe, such as had been presented by Dr. Burchard, was a very dangerous procedure. A much safer method would be, where there was strong suspicion that the gut was diseased, not to liberate it from within outward, but to

CUT FROM WITHOUT INWARD, UNTIL FINALLY THE STRANGULATED PART WAS EXPOSED,

without having been previously touched. To practise the open incision direct from without inward, and practically make the operation a laparotomy, was much safer than the old method of invagination with the finger, or the introduction of a director and conducting the dissection in that manner. Hemorrhage, also, would be avoided.

Dr. Burchard said that such instruments could be used with only the most extreme delicacy. He had not had any occasion to regret their employment, and there were certain cases in which he had found it impossible to get the finger in, or to draw the gut away from the sac, so that the dissection could be carried on. In those cases he would prefer to use such a director rather than make an open incision. He had approached the intestine in three cases as Dr. Gerster had indicated, and it was the preferable method, although it required an extensive dissection.

Dr. Gerster said that in nineteen out of twenty cases he had encountered adhesions in or near the neck of the sac, especially about the anterior wall; and he had found adhesions between the omentum and the testicle in one case, but he had not found them at the bottom of the sac.

Dr. De Garmo thought it impossible to tell exactly where the adhesions were, unless they could be felt to yield under manipulation. He was not able to state positively that there were adhesions in more than one of his cases in the vicinity of the testicle.

The President spoke of Bernay's method of dividing Poupart's ligament, and asked if anyone present had had any experience with it. He thought that probably only a few cases could be operated upon in that manner, and that it looked as though we must wait for more experience on that point.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 23, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. W. P. Northrup, in behalf of candidates, presented a specimen of *laryngeal diphtheria*, and also one of *ulcerative colitis*.

The President presented, in behalf of a candidate, a specimen of *aneurism of the arch of the aorta*.

Dr. Hodenpyl presented a specimen of

CYSTIC ADENOMA OF THE OVARY,

removed post-mortem from the body of a woman, sixty-eight years of age, who died two days after admission to the hospital. The abdomen was greatly distended, and contained a small quantity of bloody serum. The small intestines were adherent to the tumor, and greatly distended with fluid fæces. Attached to the uterus was a small fibroma. The left ovary was cystic. In place of the right ovary was the large tumor presented, which contained several quarts of dark, offensive fluid that contained pus-cells, detritus, and crystals of cholesterine. The liver was also presented, which was considerably deformed, probably from pressure of the tumor and the distended intestine.

Dr. Mary Dixon Jones presented a

UTERINE FIBROMA,

removed by operation from a patient thirty-five years of age, and the mother of one child about twenty years

of age. Her greatest suffering had been during the last six or seven years, and for three days and nights each month she had suffered from severe pelvic pains, with profuse hemorrhage, the flow continuing, in varying quantity, about fifteen days, and leaving her prostrated for the remainder of the month. During the last two or three years she had had profuse menorrhagia.

Dr. Jones saw the patient first in August last. She entered the hospital in October, and under rest, good nourishment, and careful nursing her general condition improved. At the end of three weeks an examination was made, when it was found that the tumor had diminished in size considerably. Bearing in mind that Emmet and others had reported cases in which large uterine fibromata had decreased in size, this plan of treatment was continued. The patient, however, began to get worse—the tumor pressed upon the rectum, etc.—and hysterectomy was performed on November 15th, through an incision five inches in length. The tumor began at the internal os, and was quite low in the pelvis. There were some adhesions upon the left side, and two or three par-ovarian cysts. Before the pedicle could be reached, the tumor was enucleated. A temporary clamp was applied, and afterward Koeberlé's serre-nœud was used. A drainage-tube was employed. The woman made a good recovery and was very comfortable, except that the short pedicle seemed to pull upon the abdominal walls.

Dr. Jones suggested a modification of the operation, by first liberating the vaginal wall, then opening the abdominal wall and removing the entire organ; then closing the abdominal wound entirely and leaving the vaginal opening, as the most natural mode of effecting drainage. She queried whether or not such a tumor could have been benefited by electrolysis. She thought that intra-uterine galvanic cauterization might be more dangerous than the operation.

Dr. H. J. Boldt thought it well to try electricity in these cases, as it would frequently relieve symptoms, although the most successful treatment was doubtless by operation.

Dr. Ira Van Gieson demonstrated microscopic sections of the cortex of the brain and cerebellum which illustrated

GOLGI'S SILVER PROCESS OF STAINING GANGLION-CELLS.

The technique of Golgi's methods (*American Journal of Mental Diseases*, May, 1887) is as follows:

1. *The silver process.*—Small pieces (one to two cubic centimetres) are placed in a two per cent. solution of potassium bichromate (or Müller's fluid), which is increased in concentration at each renewal of the fluid up to five per cent. There is no definite length of time for the hardening process. In summer, portions of the brain are hardened fifteen to fifty days; in winter, five to sixteen weeks. The hardening may be hastened by replacing a part of the Müller's fluid by Erlicki's fluid in increasing proportions, or by conducting the after-hardening in a mixture of eight parts of a two and one-half per cent. solution of bichromate and two parts of a one per cent. solution of osmic acid.

The hardened portions are placed, for twenty-four to thirty hours, in a large volume of a solution of nitrate of silver, which varies in strength according to the duration of the hardening—the more protracted the hardening the stronger the solution—up to one per cent. The silver solution must be changed at intervals until the chromate of silver precipitate no longer forms. The sections are washed in alcohol and cleared first in creasote, and then in turpentine. During the hardening it is advisable to test portions occasionally with the silver solution, for the method is somewhat uncertain in its results.

2. *The sublimate process.*—The same results may be obtained if the hardened pieces are immersed for several weeks in a one-half per cent. solution of bichloride of mercury. This method has the advantage of staining very large masses *in toto*.

These methods stain the ganglion and neuroglia cells, with their intricate network of processes, a deep black color and leave the basement substance nearly colorless.

Remarks.—In interpreting the results of Golgi's methods there is a possible source of error, viz., the tendency of some metallic precipitations not to be strictly confined to the cell protoplasm. The frequency with which certain metallic precipitations occur in spaces and in fluids around the cell protoplasm, in other tissues than the brain, requires great caution in deciding whether some of the delicate black lines connected with the ganglion-cells really indicate the presence of processes.

ACUTE IDIOPATHIC NEPHRITIS IN AN INFANT.

Dr. J. Lewis Smith presented specimens with the following history. They were removed from the body of an infant, aged thirteen months, an inmate of the New York Foundling Asylum. The baby was wet-nursed until November 1, 1887. In July it had a febrile movement that continued three or four days, without known cause; at one time the temperature reached 105° F. In August it had pertussis, which ran the usual course. On November 1st the child was apparently perfectly healthy. It was then "farmed out," and was away one week, when it was returned, nearly in collapse, having vomited almost all the nutriment given to it. The stools were infrequent, and were not unhealthy in consistence. There was no evidence of primary cerebral or meningeal disease. The urine was scanty, heavily loaded with albumen, and contained granular casts. Death occurred on November 21st, of probable uræmic poisoning. From November 9th to the 21st the child's temperature fluctuated been 100° F. and 105° F. Dr. W. P. Northrup, curator, made the autopsy, and found that there was moderate pulmonary inflammation, no gastro-enteritis, and no evidence of cerebral disease. The ascending colon near the ileo-cæcal valve was markedly hyperæmic. The kidneys showed the lesions of acute nephritis.

Dr. Smith said that one point of interest in the case was the occurrence of what seemed to be *idiopathic nephritis*, which had been regarded as a rare disease in early life.

The only disease of which there was any history in the case was

PERTUSSIS,

and nephritis could not be regarded as a sequel of that affection. He was inclined to the opinion that idiopathic nephritis in young children was not so frequent as might be supposed from the published cases, and that in a certain proportion of those cases there had been an overlooked mild attack of diphtheria or scarlet fever to which the kidney disease was due. It had been taught that the occurrence of nephritis as a sequel of measles was rare. He had never seen a case in private practice, and thought that if it occurred it must be very mild.

Dr. J. C. Peters had encountered numerous cases of nephritis secondary to scarlet fever, which had been overlooked, and in one patient who was eighty years of age.

Dr. W. P. Northrup had met with one case of

ACUTE DIFFUSE NEPHRITIS,

in a child *five months of age*, that had been under such observation as made it certain that it had never had any other disease.

Dr. Peters referred to the high rate of mortality from measles last year and this, according to the records of the Health Department.

Dr. Satterthwaite had supposed it to be generally accepted that nephritis was secondary rather than primary, and he had always held that scarlet fever, measles, and diphtheria were the regular precursors of Bright's disease. He had believed that acute parenchymatous nephritis in children was always secondary.

Dr. W. H. Porter said that many patients died with the ordinary clinical symptoms of uræmia, but without either casts or albumen in the urine prior to death. In such cases the kidneys were large, the epithelia were

swollen and granular, and unquestionably the organs were unable to eliminate the effete material which they were called upon to remove.

Dr. T. E. Satterthwaite presented two microscopic slides from a specimen of

LARYNGEAL CARCINOMA,

with the history of the case and remarks on the *value of the microscope in diagnosis.*

"I think it is an opportune moment to bring before this Society a topic that is now very properly agitating medical minds, viz., the value of microscopic examinations in cases of malignant diseases. And I do so more particularly at the present time, because of a recent discussion at a society meeting in which I took part, and where an effort was made to contrast clinical diagnosis with microscopic, and to the discredit of the latter.

"But now the unfortunate issue of a certain case across the water, belying as it does the printed reports of an eminent pathologist, may with reason set the current back against those who have been working for years past to erect microscopic diagnosis into

A DEPARTMENT OF SCIENTIFIC MEDICINE.

"I therefore take the opportunity of exhibiting two slides, and give the history of a case which furnishes an interesting lesson, from which can be derived valuable corollaries. The history is condensed from the records of the Presbyterian Hospital.

"D. O'L——, aged sixty-three, Ireland, married, entered the hospital February 22, 1886. He had enjoyed remarkably good health until nine months previously, when he swallowed a small fish-bone, which he described as 'thread-like.' Immediately afterward he began to suffer pain in the windpipe, and spit up 'blood and matter.' After two days' suffering the pain abated, so that the bone was suffered to remain undisturbed. Two weeks later pain recurred in the same spot, and after an interval of two months he began to lose his voice. At this time he consulted several specialists, and the solid nitrate of silver in stick form was several times applied to the throat. After about seven months he had some dysphagia, and since that time took no solid food, spoke but little, and gradually lost flesh and strength. About the eighth month he had a severe hemorrhage, losing about a cupful of blood in a few minutes.

"On admission he was found to be suffering a good deal of pain. There was also marked stridor and dyspnœa. Breathing best when lying down. Does not speak above a whisper.

"Laryngoscopic examination showed a swelling of both arytenoids, especially of the left, and of the right ary-epiglottidean fold.

THE TUMOR WAS GRAYISH ON THE SURFACE, WITH SCATTERED SMALL RED SPOTS.

"No paralysis of the cords. Larynx tender on pressure. Further examination showed that the liver was not enlarged. No sternal or tibial tenderness. No nodes. Cervical glands somewhat enlarged. A consultation was held between the hospital surgeons, prominent specialists being also present. Opinions were divided, one-half holding that the affection was inflammatory, due to the lodgment of a foreign body; the other half, comprising the hospital surgeons in attendance, making a diagnosis of

LARYNGEAL EPITHELIOMA.

"On the day following tracheotomy was performed. The laryngeal cavity was made plainly visible, and the new growth was seen to involve, not only both sides of the larynx, but also to extend downward in the wall of the trachea as far as the rings were cut.

"Portions of the growth were then removed for microscopic examination, and the tracheotomy tube was inserted. The operation gave relief, but the patient died three months later, probably of exhaustion from the extension of the disease.

"At post-mortem examination the right lung was found strongly adherent to the chest-walls; the left lung was slightly adherent at base and apex. The heart, lungs, larynx, tongue, and œsophagus were removed *en masse.* The œsophagus was free from disease, except at a point where it was in close relation with the laryngeal disease, where its coats were slightly infiltrated. The inferior half of the laryngeal cavity was occupied by papillary and nodular growths, which had completely or nearly occluded its lumen. The lower part of the growth was in an ulcerated and sloughing condition, and portions of the cricoid and thyroid cartilages had been destroyed by the disease. The walls of the trachea were infiltrated half-way from the larynx to the bifurcation. The cervical glands of the left side were found enlarged. The lungs appeared to be free from secondary deposits. The heart, spleen, kidneys, and liver showed no implications.

"This case is interesting to me at the present time for an especial reason, viz., because the papillary and nodular growths were several times examined in my laboratory, by myself and assistants, and

NOTHING CANCEROUS WAS FOUND;

and yet the post-mortem examination revealed in the enlarged and infiltrated cervical glands the characteristic cell-formations exhibited under the microscope.

"With this case in view, it may be well to emphasize the fact that one cannot be too cautious in the delivery of an opinion in such cases, especially where the papillary or villous growth is the only part that is submitted for examination. And I presume that this opinion is held generally in New York.

"Indeed, I think it is generally admitted that one should never give an opinion in such instances unless the evidences are unmistakably in favor of this or that growth. It often happens that one instantly stumbles upon such microscopic proof that the diagnosis is made at once, and yet one may not be so fortunate, and for very good reasons: (1) At the inception of the disease the pathognomonic evidences are absent, or are so slight that they may be overlooked. (2) There is always a focus of the disease in which these characters are seen after, to the exclusion of more distant parts. (3) In a growth that is growing rapidly and ulcerating, the characteristic tissue may be constantly sloughing off.

"But I would not wish it understood that the statements tend to depreciate the value of the microscope. It has its field, in which it is of paramount value, but it is a limited field; and it should not be relied upon in every instance to the exclusion of clinical signs—and yet it is in this class of cases that the microscope often gives the most brilliant results. But when it fails it is usually because the pathologist is not furnished with a sufficient amount of tissue on which to base his opinion.

"In this connection I would venture to state that, in my humble opinion, the real error in the diagnosis of carcinoma among ordinary competent microscopists is very small. On page 329, vol. iii. of our Transactions, I put it that one per cent. is the figure. A single mistake only occurred in a hundred cases reported by myself, working conjointly with Dr. W. H. Porter. In that instance the specimen sent for examination had been changed by decomposition."

The President remarked, with reference to the case which all had in mind, that those who had made adverse criticisms on Virchow had overlooked entirely the fact that a benign growth may be followed by a malignant one.

Dr. Satterthwaite raised the question,

IS NOT THE MICROSCOPE COMPETENT TO MAKE A DIAGNOSIS WITH REGARD TO THE VARIETIES OF CARCINOMA?

The question was answered in the affirmative by the President and by all those present who had had practical experience in the use of the instrument.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GENERAL MEDICAL COUNCIL—REMOVAL OF OFFENDERS FROM THE REGISTER—A SELF-DENYING ORDINANCE—THE BROWN LECTURES ON HYDROPHOBIA—SYMPTOMS AND MORBID ANATOMY OF THE DISEASE—DISCUSSION ON THE TREATMENT OF EXTRA-UTERINE PREGNANCY.

London, December 6, 1887.

The General Medical Council have concluded their session. I find that I was in error in stating the case of Mr. Partridge, the advertising dentist. This gentleman (who was a dental licentiate of Dublin, not of Edinburgh) won the day, it is true, as regards his contention that in his case a dental diploma was not essential to his remaining on the register. The Council, however, have still power to remove him for "infamous conduct," and they have done so on that ground. Mr. H. A. Allbutt (who must not be confounded with Dr. Clifford Allbutt) has met with a similar fate for publishing a Malthusian work which, in the opinion of the Council, is both indecent and immoral. The last day of the session was occupied in discussing the finances. These, it appears, are not satisfactory, or likely to be. Some members of the Council have, *mirabile dictu*, proposed to solve the difficulty by reducing their own fees. This is almost too good to be true.

In the second Brown Lecture the symptoms of rabies in man and other animals were described. Different animals exhibited different manifestations of the disease, and it had hence been supposed that the poison might be of a different nature in different animals. Mr. Horsley, however, thought that the difference was simply due to the animal in which the virus was acting, and that this was always one and the same. Two stages of the disease had been noted. The first was one of excitation; the second, one of paralysis. The latter was marked by the dropping of the jaw and weakness of the hind legs. The animal stood with legs apart as if to steady himself. Finally he lay down totally paralyzed. In rabbits the stage of excitation was but slightly marked; the symptoms being almost entirely those of paralysis. Photographs of different animals were shown upon the screen illustrating these various conditions. In man the stage of paralysis had been overlooked until the last few years. It was, however, clearly marked if the patient lived long enough. An interesting case was mentioned by the lecturer. A patient in India suffering from rabies had had the spasms in the throat subdued by constant applications of cocaine. He lived nine days, and finally died with symptoms closely resembling those of acute ascending paralysis (Landry's paralysis). From this and other cases some observers had concluded that this disease was simply masked rabies.

In dogs the bark was a characteristic feature of rabies. It had been described as resembling a groan. In any case, it ended in a falsetto note. As laryngitis was very rare in dogs the modification of the bark was a very important sign.

The mode in which the poison entered the system was then discussed. As the period of incubation was so long, it could not be by the blood-vessels. It was probably not by the lymphatics. It had been held by some that the poison entered the system through the nerves. Experiments had shown that when the poison had been introduced into the fore limbs of an animal, that end of the spinal cord had first been affected by the poison. In pregnant animals dying from rabies the nervous system of the fœtus had been (by means of Pasteur's method) shown to contain the poison.

In the third lecture the morbid anatomy of the disease was considered. No changes had been found in animals killed during the period of incubation, and it was an important practical point that the bite of an animal which had been inoculated with the poison would not convey the disease previous to the manifestations of symptoms in the animal inflicting the bite.

Passing on to the consideration of the morbid changes found in animals dying from rabies, Mr. Horsley remarked that no changes had been found in the serous membranes. Nor had any changes been met in the vascular system.

Hemorrhages into the stomach were often found. Congestion of the nervous system was pretty constant, and the so-called "miliary abscesses" were frequently seen. It had been stated that, in dogs, foreign bodies in the stomach were often seen, but the lecturer showed that this was not a sign of rabies only, for dogs suffering from other diseases had morbid appetites and would eat strange substances which came in their way.

A special meeting of the Obstetrical Society was recently held to discuss the treatment of extra-uterine pregnancy during the latter months. Dr. Herman read a paper on delivery by the vagina, which might, he thought, be effected in some cases with advantage. It was contraindicated early in pregnancy, or soon after rupture had taken place when interference was called for to arrest hemorrhage, abdominal section then being preferable. At, or soon after full term, before suppuration had taken place, there might be conditions which indicated delivery by the vagina as preferable to abdominal section. These were: (*a*) When the fœtus was presenting with the head, breech, or feet, so that it could be extracted without altering its position. (*b*) When it was certain, from the thinness of the structures separating the presenting part from the vaginal canal, that the placenta was not implanted on that part of the sac, and it was not certain that the placenta was not implanted on the anterior abdominal wall. If turning were required, abdominal section should be performed. No attempt should be made to remove the placenta. The after-treatment should consist in frequent washing out of the sac. After suppuration had taken place, the spontaneous opening of the sac into the vagina was one of its more favorable terminations. Dr. Champneys read a paper on primary laparatomy (the child being alive), and Dr. John Williams related a case in which abdominal section was performed at the thirty-fifth week. Mr. Knowsley Thornton remarked that the question of primary laparotomy hinged on perfect diagnosis, and, knowing how often there was something wrong with the child in these cases, he would disregard it and simply consider the mother. The President (Dr. John Williams) observed that the risks of laparotomy during the life of the fœtus were those of septicæmia and hemorrhage. Antiseptics had greatly lessened the former. Mr. Lawson Tait alluded to the danger of hemorrhage which he considered was not much, with modern methods of controlling it. As to the growth of the placenta after death of the fœtus, he used to disbelieve it, but was now convinced that it occurred in a great number of cases. That being so, what was the use of destroying the fœtus by electricity as the placenta continued to grow?

THE RECOGNITION AND TREATMENT OF INSUFFICIENCIES OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In your issue of the 17th appears a communication from Edward Loring, M.D., in which he criticises the report of my paper on "Problems respecting Insufficiencies of the Ocular Muscles," read before the International Medical Congress. Had the writer taken the trouble to wait for the publication of the paper itself rather than satisfy himself with the report, necessarily brief, which appeared in your summary of the proceedings of the Congress, he might have found reason to suspect that there are still

important problems worthy of solution respecting the so-called "insufficiencies" of the ocular muscles.

My critic cites the case in which, with an adducting power of 50°, there existed "insufficiency" of the externi 8° for twenty feet, and of the interni 10° at one foot; also the instance in which diplopia, homonymous at twenty feet, and crossed at two feet, existed. His communication would lead his readers to suppose that these apparently opposite conditions are consistent with the theory of actual insufficiency of the externi for distance and of the interni for near.

Now, it would not require the aid of the highest mathematical calculations to demonstrate that such conditions as are found in these two cases are entirely inconsistent with the theory mentioned. I venture the statement that neither the critic's "illustrious predecessors" nor any of his "*confrères*" have given a satisfactory explanation of this class of phenomena, which is very frequently encountered. It is true that in the paper reported in THE MEDICAL RECORD I have ventured to suggest the direction in which it appears probable that we must search for the exact answer to some of the perplexing questions which arise in cases of this class, but it is safe to assert that they are still far from being fully answered.

While strongly impressed with the necessity of an acquaintance with, and due respect for, the principles "inculcated and practised" by our "illustrious predecessors," I can conceive of no reason for an unquestioning acceptance of all their views and methods as being final and complete.

Regarding my statement that in the literature of ophthalmology "insufficiencies" of other muscles than the interni have been largely if not practically ignored, and for which this critic takes me to task, one has only to open to the brief chapter on Muscular Asthenopia in any of the text-books on the eye, in most common use, to assure himself of the entire correctness of my statement. Taking up twelve recent comprehensive text-books on the Diseases of the Eye by well-known authors, German, French, English, and American, including those cited by your correspondent, I find an average of three pages devoted to the subject of muscular asthenopia; and in only two of these works, which, by the way, are the two quoted by him, is there a recognition of any insufficiency but of the interni in the causation of the complaint. Even in one of the two works quoted by your correspondent, the existence of a single other insufficiency is barely recognized. Landolt, in his excellent work on Examination of the Eyes, devotes five pages to muscular asthenopia, but alludes to no insufficiency but that of interni. It is also a significant fact in this connection, that the principal periodical in this country devoted to ophthalmology has, during the sixteen years of its publication, contained no article on muscular insufficiencies until within the past year. It is true that text-books are but the summary of the literature, yet they fairly reflect the drift of current discussions. Had your correspondent read the paper which he criticises in advance, he would have seen that the physiological fact of the relation of the axes was not forgotten, but fully recognized. If the problems suggested in the paper are understood by the "ordinary student of ophthalmology," I have the most positive reasons for believing that they are not so clear to many whose accomplishments entitle them to high rank as students in this branch of science. It is perhaps true in this department of research, as in others, that the "ordinary student" is wiser in his own conceit than the investigator who is sufficiently informed on the subject to understand its difficulties. The truth is that no one not oppressed with a superconsciousness of his own accomplishments can for a moment suppose that there are no further problems in the subject of the relations of the ocular muscles, a subject of great if not of equal interest with that of refraction, and surrounded with many intrinsic difficulties, yet which has received, compared to the subject of refraction, but meagre attention.

That a much greater interest is being awakened respecting this subject is a gratifying fact. As one of many evidences of increased attention to these muscular conditions, I may mention that in one of the most important of the eye hospitals in this city more operations for tenotomy of the ocular muscles, in cases of insufficiencies, have been performed during the past year than during its whole previous history of many years. This is a sufficient answer to my critic's statement that all oculists of this city have for twenty years operated for all cases of insufficiency as occasion has arisen.

The *argumentum ad hominem* which appears to form the central idea around which the letter of your correspondent revolves is quite unworthy of comment.

GEORGE T. STEVENS, M.D.

33 WEST THIRTY-THIRD STREET.

THE NEW YORK LICENSING AND REGISTRATION ACT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a late issue of your valuable journal appeared a reprint of the act regulating the licensing and registration of physicians and surgeons, passed by the late Legislature.

While doubtless satisfactory to the profession, its intent is not quite clearly expressed, and an amendment is needed by prefixing the word "but" to the fourth section.

The learned counsel who drew up the bill in question has written me, in effect, that Section 4 was intended to apply, in short, to the cases referred to therein; but, unfortunately, Section 3 remains unmodified, and lately I was refused registration in a neighboring county, although I sent my New York County certificate to the county clerk, who insists upon my appearing in person, displaying my diploma for his personal inspection, and presumably paying him an additional fee, as provided by law.

The Secretary of State writes me that he thinks I am right, but doesn't like to give an official decision upon a statute which may have to be determined by the courts.

What am I to do? The county clerk is obstinate, and so am I. Can not we have the act amended in Albany, by the insertion of some such little word as suggested? It may save some poor doctor from getting into trouble, or some county clerk.

MEDICUS ERRATICUS.

MERCURIAL HYSTERIA.—Dr. Letulle has collected the reports of a number of cases of hysterical symptoms occurring in patients who had been taking mercury for a considerable length of time. The affections were similar to those sometimes seen associated with lead poisoning. The author believes that lead and mercury, as well as alcohol, favor the outbreak of hysterical symptoms in those who are predisposed to this neurosis.—*Revista de Medicina y Farmacia*, November 18, 1887.

IMPROVED BLAND'S PILLS.—Dr. W. Coe McKeeby, of Port Jervis, N. Y., writes: "Having heard many complaints from physicians of the large size of Bland's ferruginous pills, made by different pharmacists, I suggest the following formula, which will always give the same-sized pill (small), viz.:

℞. Ferri sulph. cryst.,
Potassii carb. .....āā 3j.
Sacch. albæ..... ℈j.
Acaciæ pulv..... grs. xv.
M. Ft. pil. no. xl., sec. artem.

Mix the iron and potassium in a mortar until the chemical change takes place. Then add the sugar and acaciæ, and mix until a mass is formed. Then roll into the number of pills required, and coat with a solution of tolu in sulphuric ether."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 11 *to December* 17, 1887.

BANISTER, W. B., First Lieutenant and Assistant Surgeon. Ordered to proceed at once from Fort Lowell, Ariz., to Fort Wingate, N. M., and report to the commanding officer for duty. S. O. 128, Department of Arizona, December 1, 1887.

HARRIS, H. S. T., First Lieutenant and Assistant Surgeon. Ordered from Fort McIntosh to Camp Pena, Colorado, Tex.

CLENDENIN, PAUL, First Lieutenant and Assistant Surgeon. Ordered from Camp Pena, Colorado, Tex., to Fort McIntosh, Tex. S. O. 143, Department of Texas, December 12, 1887.

CABELL, J. M., First Lieutenant and Assistant Surgeon. Ordered for duty at Fort Niobrara, Neb. S. O. 286, A. G. O., December 9, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending December 17, 1887.

HUDSON, A., Medical Inspector. Ordered to the Trenton.

BATES, N. L., Medical Inspector. Detached from the Trenton, and placed on waiting orders.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 17, 1887:

	Cases.	Deaths
Typhus fever	0	0
Typhoid fever	16	3
Scarlet fever	126	23
Cerebro-spinal meningitis	5	3
Measles	29	6
Diphtheria	196	49
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

POISONING BY SELTERS WATER.—Over thirty cases of poisoning were reported recently in Rendsburg, and the occurrence, of course, occasioned great excitement in that quiet German city. Inquiry showed that only those were poisoned who drank freely of Selters water, and an examination of this water revealed the fact that it contained a very appreciable amount of arsenic. The water was a manufactured product, and had been imported from another city.

AN EMBRYOLOGICAL PRIZE.—The Academia dei Lincei, of Rome, offers a prize of one thousand francs for the best essay on embryology, which is open to universal competition. The essay must be written in Italian or Latin, and is to be presented on or before December 31, 1888.

AN INTELLIGENT VERDICT.—A coroner's jury in England, so reports a French exchange, sitting upon the body of an executed criminal, brought in a verdict of death from fatty degeneration of the heart, accelerated by strangulation.

PHYSICIAN TO THE EMPRESS OF RUSSIA.—Dr. Botkin, the physician to the Czarina of Russia, is said to have obtained his appointment by the exhibition of a little independence. He was called one day, so the story goes, to the Winter Palace, to prescribe for her imperial majesty, who was suffering from a cold. But the empress refused to disrobe sufficiently to allow him to auscult her chest, whereupon Dr. Botkin took his departure, saying that he didn't care to have anything to do with patients of that kind. The Czar was so pleased with this manifestation of spirit on the part of the physician that, instead of sending him to Siberia, he recalled him and appointed him special physician to the empress on a yearly salars of 100,000 rubles.

A LEGACY of the value of eight thousand dollars has been left to the Académie des Sciences by Mme. Foehr, who died recently in Paris. The interest on this sum is to constitute a prize to be awarded annually for the best essay on some subject connected with the healing art.

A PLEASANT VACATION.—M. Trélat, a French medical professor, has been sent on a mission to Constantinople and Athens, to visit and report on the scientific, medical, and charitable institutions in those two cities.

ANALGESIC EFFECTS OF HOT-WATER INJECTIONS.—M. Tripier, of Lyons, reports a speedy relief in cases of lead colic by rectal injections of water at a temperature of 113° to 118° F. Equally good results were obtained in the fulgurating pains and rectal and vesical tenesmus accompanying locomotor ataxia. In dysentery, also, these injections have been found to be of the greatest benefit.

TRICHINOSIS IN HAMBURG.—A number of persons in Hamburg have been attacked with trichinosis after eating ham. The authorities have seized large quantities of infected pork.

EXTEMPORANEOUS EMULSION OF CASTOR-OIL.—M. Léger states that the casein of milk possesses the property of emulsifying oils. The casein is prepared by adding to it a little bicarbonate of soda and powdered sugar. He proposes the following formula for a palatable extemporaneous emulsion of castor-oil: Castor-oil, 15 parts, cherry-laurel water, 5 parts; distilled water, 100 parts; prepared casein, q. s. This emulsion is said to have an agreeable taste, and to be well borne by the weakest stomach.

AXILLARY ADENOPATHY AND PULMONARY TUBERCULOSIS.—Dr. Grancher states that he has frequently found the axillary glands involved in cases of tuberculosis of the lungs. He says that the existence of enlarged glands in the axilla should always direct attention to the possibility of pulmonary disease, and when this is found to be present the removal of the affected glands will serve no good purpose.

CEPHALALGIA AND PHARYNGITIS.—Dr. P. Vergely, writing in the *Journal de Médecine de Bordeaux*, Nos. 6 and 9, 1887, states that he has found pain in the neck and posterior portion of the head very frequently associated with affections of the pharynx. This pain is often exceedingly rebellious to direct treatment, but yields readily to remedies applied to the relief of the pharyngeal affection.

THE CONVERSION OF BENIGN GROWTHS OF THE LARYNX INTO MALIGNANT.—At the recent Congress of the German Naturalists and Physicians Professor Schnitzler read a paper upon the subject of the "Malignant Degeneration of Benign Growths in the Larynx." He first described a case of epithelial carcinoma with secondary growths in the lymphatic glands and pleura, in a patient who some months previously had been operated on for papillomata, the recurrence of which had been treated by cauterization. The patient subsequently came under Professor Schnitzler's care with symptoms of perichondri-

tis, but the carcinomatous nature of the disease was recognized, and the supervention of pleurisy some weeks later was considered to be due to a diffusion of the malignant disease. This diagnosis was confirmed after death, when, besides the laryngeal and pleural carcinoma, there were found necrosis of the thyroid cartilage and gangrene of the right lung. Professor Schnitzler remarked upon the rarity with which benign tumors take on malignant characters, he having seen such conversion only three times among hundreds of cases of laryngeal papillomata. He left undetermined the question whether the operations and frequent cauterization induced the malignant disease, and said that endo-laryngeal operations upon papillomata should be discountenanced on this ground. He also spoke of the difficulty in the differential diagnosis between benign and malignant growths, as well as between laryngeal syphilis and carcinoma. Dr. Morelli related the case of a man whose larynx was so blocked by papillomatous growths as to necessitate tracheotomy prior to a thyrotomy, with complete ablation of the new growth and galvano-cauterization of the laryngeal wound. The patient left, apparently cured, but wearing the tube. After the lapse of a year he returned with evident carcinomatous degeneration of the papilloma, which filled the larynx to the level of the tube, which was partially displaced and blocked by it. This was the only case of the kind that Dr. Morelli could recall within a period of nearly ten years. Dr. Seifert referred to a case published by Böhmer, where papillomata (histologically examined) had been treated by Professor Gerhardt and himself for a year, but which passed into carcinoma, for which extirpation of the larynx was practised; but the patient did not long survive the operation.

Evil Communications Corrupt Good Manners.—Dr. Charles L. Lang, of this city, writes: "A few weeks ago, to economize space, I put a small roll of rubber adhesive plaster into the same tin cylinder with a roll of emplastrum cantharides. The other day I applied a strip of the adhesive plaster to a carbuncle on the nape of the neck, and when I removed it the next day, considerable of the cuticle came with it. I afterward applied another strip to an enlarged and painful inguinal gland, but the patient complained at the end of a few hours that the plaster smarted, so I took it off, revealing a raw or blistered surface the size of the plaster. This clearly shows the effect, upon even adhesive plaster, of keeping bad company."

To Relieve the Pain of an Aching Tooth.—Dr. Popoff (*Russkaya Meditsina*) recommends a solution of potassium permanganate, one part to five hundred. A little of this solution should be held in the mouth, in contact with the aching tooth, for a few minutes, the application being repeated every half-hour.

Is this a Specimen of French Gallantry?—According to the *Medicinische Wochenschrift*, of St. Petersburg, the appearance of a female medical student, who presented herself for examination, was the occasion of a disgraceful performance on the part of the male students of the École de Médecine of Paris. They made such a noise with cat-calls and whistles that it was impossible to proceed, and the lady's examination was postponed to another day.

An Inebriate Asylum, the first of the kind in Russia, has recently been established in one of the cities of that empire. It has accommodations, as yet, for only five inmates. If the tales of travellers in that country are to be credited, this asylum will most truly "fill a long-felt want."

A Reminiscence of Sir Fielding Ould.—The honors, few and insignificant though they were, granted to medical men on the occasion of the jubilee of Queen Victoria, recall to a correspondent the knighthood conferred upon Fielding Ould, the successor of Dr. Mosse, the founder of the Rotunda Hospitals, in Dublin. Mr. Ould was an obstetrician of great celebrity, and it was he who delivered the Countess of Mornington of the future Duke of Wellington. On the occasion of his receiving the knighthood the London *Lancet* had the following:

> "Sir Fielding Ould is made a knight,
> He should have been a lord by right;
> For then each lady's prayer would be,
> 'O lord, good lord, deliver me.'"

A Possible Cause of Left-handedness.—Dr. Feltz relates the following in *L'Art Médical*, of October 2, 1887: In a family composed of five persons, the father and mother were right-handed, as was also the eldest son, who was always cared for in his infancy by a nurse. The second child had been nursed by the mother, and was left-handed. The third child, also nursed by his mother, was, at the age of one year, evidently left-handed, never grasping any object with his right hand. Dr. Feltz noticed that the mother carried the child on her left arm, and she said, in reply to his questioning, that it had always been her custom to carry her children on this arm. The writer advised her to hold the infant on her right arm. She did so, the baby soon began to use his right hand in seizing objects, and is now, at the age of ten years, normal as regards the preference of the right over the left hand. When the nurse carries the child on her left arm, Dr. Feltz remarks, the left arm of the infant is the one which is free, and which consequently he learns to use to the neglect of the right.

Medical Cowards.—Some of the physicians of Sicily have shown themselves to be made of pretty poor stuff. Not only the mayors and other officials, but also many of the doctors in several of the small towns in the provinces of Catane and Syracuse, Sicily, ran away upon the approach of cholera. The *Official Gazette* of August 13th published the names of those physicians and pharmacists who had deserted their posts through fear of cholera, and the total number of names amounted to fifty. Possibly, however, the insane fury with which the Italian peasants pursue the physicians, in times of cholera, had as much to do with the flight of the latter as did the fear of the disease. It is one thing for a physician to fight disease, of however deadly a nature it may be, and another to stand up against a howling mob of panic-stricken lunatics, who are bent on taking his life.

Longevity in Italy.—According to the last Italian census, the number of persons over seventy-five years of age in that country was 381,229, of which 195,997 were men and 185,232 women. The proportion of individuals over seventy-five years of age to the entire population was 13 per 1,000. In Liguria the proportion was 19 per 1,000, while in Latium it was but 9.

Restricting the Number of Medical Students in Russia.—According to a recent decree, the number of medical students in the University of Moscow will hereafter be limited to two hundred and fifty. Of this number the proportion of Jews shall not exceed three per cent. In addition to this, the fees of medical students have been increased by twenty-five rubles a quarter. As the greater number of students in the medical department are from the poorer classes, this increase will have the effect of still further restricting their numbers. These measures are not taken because there are too many physicians in the country, for the contrary is the fact, but because the medical students are among the most active in the nihilist propaganda.

The Chinese Treatment of Hydrophobia.—In China, so it is stated, when a person who has been bitten by a mad dog begins to show signs of rabies, he is strung up by the hands and feet, and left in this comfortable position until recovery or death ensues. No better results are reported from this than from Pasteur's method of treatment.

SOME UNUSUAL MUSCULAR ANOMALIES.[1]

BY FRANK BAKER, M.D.,

PROFESSOR OF ANATOMY, MEDICAL DEPARTMENT OF GEORGETOWN UNIVERSITY, WASHINGTON, D. C.

I HAVE to present to the Society to-night an account of a series of muscular variations found in a single subject, some of which, taken singly, might be deemed of interest, and in combination are certainly most rare and instructive.

The individual in whom these variations were found was a Caucasian, probably of Irish birth, and about seventy years of age. As far as can be ascertained there was nothing unusual in his manual aptitude, although he was noted for being somewhat "handy."

On laying bare the muscles of the chest it was seen that on one side there was a marked interval between the sternal and the clavicular portions of the pectoralis major. The separation was quite as distinct as that between the pectoralis and the deltoid, and resembled the condition found in the gorilla and the orang, which have two distinct muscles between which passes a prolongation of the air-sac.

Besides this variation, of comparatively slight importance, another rarer one was found on turning back the muscle, viz., a separate sheet of muscular fibres arising by three digitations from the cartilages of the fourth, fifth, and sixth ribs, and passing outward to a tendon which united with that of the great pectoral at some distance from its insertion into the humerus. This sheet was entirely distinct from the pectoralis minor, which was normal. It affected only the sternal portion of the pectoralis major, the clavicular portion being undivided. This is, as far as I am aware, the third case of the kind that has ever been recorded; the others being reported by Macalister[2] and Tiedemann.[3] It appears to be the ordinary condition of the pectoralis major in the sloth, the pig, and the sheep.

Another series of variations was found in the biceps brachii of each side. Both muscles showed supernumerary heads, the arrangement of which was very instructive, as it throws light upon the origin and affinities of the muscle. The adult biceps is ordinarily, as its name implies, a muscle of two distinct origins, the coracoid, or short head, arising by a tendon common to it and the coraco-brachialis from the coracoid process of the scapula; the glenoid, or long head, from above the glenoid fossa of the humerus by a tendon which penetrates the capsular ligament of the shoulder, passes through the cavity of the joint surrounded by synovial membrane, reaches a groove in the upper portion of the humerus, and then, becoming muscular, joins about the middle of the arm with muscular fibres derived from the other head. The combined muscle then tapers to a tendon, which is inserted upon the tuberosity at the upper portion of the radius at its internal aspect.

A third head to the biceps is found about once in every ten subjects, arising usually from the inner side of the humerus, in close connection with the insertion of the deltoid, sometimes from the fascia covering the brachialis anticus, or from the intermuscular septum. This may have various relations with the great vasculo-nervous bundle which passes down the inner side of the arm, passing usually under it, sometimes over it, rarely having two portions between which the vessels and nerves pass. In the present instance this humeral head is well developed. It arises from the under part of the muscular belly, and is extended over the vasculo-nervous bundle, to be inserted on the inner side of the humerus just below the middle, its upper fibres being immediately below those of the deltoid. Some of the fibres probably passed to the fascial septum on the inner side of the arm, and thus guarded against compression of the vessels.

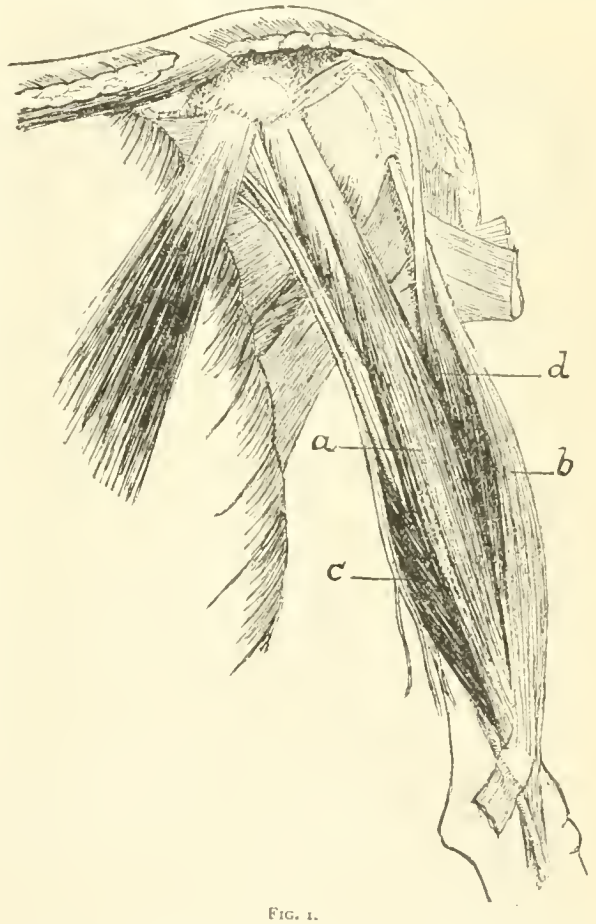

FIG. 1.

This arrangement of the biceps is apparently a case of atavism. It is found in some climbing animals where strength rather than speed is required, such as the three-toed sloth, frequently in the orang, and in bats. It is also found in the rhinoceros. Its physiological function would seem to be to add power to the muscle, on the general principle that many short fibres obliquely directed upon a tendon increase the power while effecting but slight relative displacement of the points of attachment; while long fibres, longitudinally directed, give considerable displacement, with a corresponding loss of power.

In addition to this humeral head of the biceps there were, in the present subject, two instances of a very rare variety, namely, a capsular head. On the right side the coracoid and glenoid heads were unusually separated,

[1] Read before the Biological Society of Washington.
[2] Trans. Royal Irish Acad., 1871.
[3] Journal complémentaire des Sciences médicales. 1830.

remaining ununited as far down as two inches above the elbow. About three-fourths the distance down the long head a flat, ribbon-like fasciculus came off, which was carried up separately and blended with the fascial expansion of the pectoralis major upon the outer lip of the bicipital groove, which expansion is continuous with the joint-capsule. There was no humeral head on this side.

Upon the left side the variation extended still farther, presenting the arrangement shown in Fig. 1.

Here, besides the coracoid, the glenoid, and the humeral heads, there is another passing up along the bicipital groove, but not inserted there; going, in fact, to the very outside and top of the capsule. This is given off from the coracoid head.

These last-mentioned variations are interesting as confirming the theory of Welcker with regard to the origin of the muscle. He finds that in the animal scale the biceps has three essentially different forms:

First, it lies outside the fibrous capsule of the shoulder-joint. Examples of this are found in the tapir, the horse, the mole, and other animals (Fig. 2, 1).

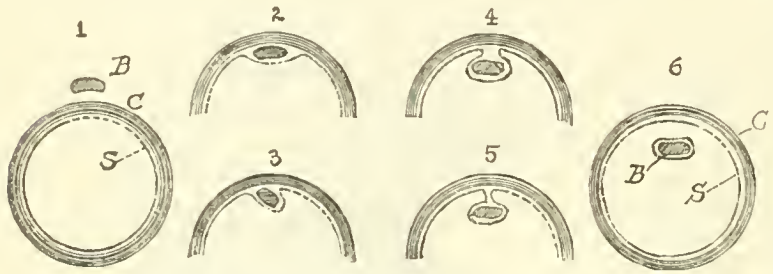

FIG. 2.—After Welcker. *B*, biceps tendon; *C*, capsule; *S*, synovial membrane.

Second, it touches the synovial membrane, and penetrates the joint to a varying depth. This appears to be a progressive formation from the previous one. A number of varying forms show this. Of these may be mentioned:

(*a*) The condition found only in embryonal states, when the tendon lies between the external capsule and the synovial membrane without embedding itself in the latter (Fig. 2, 2).

(*b*) The tendon commences to impinge upon the synovial membrane by a sideways insinuation. This is found in some bats (Dysopes tenuis—Fig. 2, 3).

(*c*) The tendon is well invaginated, but with no well-marked mesotenon (Nasua, Myrmecophaga—Fig. 2, 4).

(*d*) With a long mesotenon—(fœtal calf Fig. 2, 5).

(*e*) Tendon passes freely through joint-cavity sheathed with synovial membrane which has no mesotenon. This is the adult form in man and many mammals (Fig. 2, 6).

In examining fœtal joints this whole series is found represented. At an early stage the tendon is without the capsule; at about three months, as indicated by the drawing herewith (Fig. 3), the tendon is still attached by a duplicature of the synovial membrane constituting a mesotenon.

FIG. 3.—After Welcker. *B*, biceps tendon.

In still a third class of cases the tendon appears to lie on a recess of the joint-capsule, surrounded by a special synovial membrane of its own, which is probably to be considered as a bursa vaginalis, such as is formed about tendons elsewhere.

It will be observed that the peculiarity of the biceps which is noted here tends to confirm the notion that its tendon was originally outside the capsule and migrated to the interior of the joint. The supplementary heads here described are merely fascicles which have become detached in the migration. It is not clear how they can be of any practical benefit, unless it be to keep the capsule tense and lifted out of the way during the raising of the arm, an office usually assigned to the subscapularis.

The method of development of the biceps here indicated throws some light upon the development of tendons near joints in general. Welcker has shown that the ligamentum teres of the hip-joint is likewise subject to modification in an exactly similar manner, and Sutton[1] regards that structure as the tendon of a muscle (pectineus) which has lost its muscular elements and remains tendinous above. He also holds that the gleno-humeral ligament of the shoulder-joint is the vestige of a former condition of the subclavius, which he thinks is homologous with a muscle which, in birds, passes from the sternum to the humerus through the joint-capsule. This in man has lost its distal portion.

In some cases the biceps also has been found to have lost its glenoid insertion. In one case reported by Joessel[2] the capsule appeared to be normal and the missing head was not represented by any unusual arrangement of the fascia. The interchangeability of muscle, fascia, and ligament is too often lost sight of in considering muscular variations.

Perhaps we may also properly connect this variation of the biceps with the anomalous condition which existed in the pectoralis major. It is well known that the trunk, with its investing sheets of muscle, is formed before any limbs appear, and that these arise as lateral buds, upon which, as they push outward, the muscle-sheets of the trunk extend, first as a nearly simple and undivided layer, afterward becoming separated as distinct muscles. As the limb grows outward secondary layers of investment push out from beneath the upper ones.

The original primitive investing layer is represented by the trapezius and deltoid (originally a single muscle reaching from occiput and spine to humerus), pectoralis major, and latissimus dorsi. The primitive connection of these muscles is shown by the various anomalous conditions which they present. It is not at all infrequent to find the pectoralis major and the deltoid united into a single delto-pectoral muscle. Very often the only means of differentiation is afforded by the position of the cephalic vein, and even this fails sometimes. Cases of this kind are cited by Testut,[3] Perrin,[4] Otto,[5] Seiler,[6] Koster,[7] Ward,[8] and Flesch.[9] Muscular connections of various degrees occur between the latissimus dorsi and the pectoralis major, across the axillary space, in about twenty-five per cent. of cases.[10]

The secondary investment of the limb is formed by the biceps, coraco-brachialis, triceps, the muscles of the tuberosities, and the teres major. Anomalous connections between this set and the preceding are very numerous. It will be sufficient to cite a few. The pectoralis major may be continuous with the coracoid head of the biceps.[11] It may have a supernumerary insertion upon the brachial aponeurosis,[12] or even the inner condyle of the humerus.[13] The latissimus dorsi may blend with the teres major,[14] or send a prolongation to the coracoid process or to the capsule,[15] and even also to the inner condyle.[16]

The tendency to variation in the present case was evidently in the direction of increased specialization. The pectoralis major was more highly specialized by the differentiation of special sternal, costal, and clavicular

masses. The biceps appears to have continued the same tendency.

Besides the above-mentioned variations a number of others were found, generally in the direction of increased specialization. The dissection was not complete enough to allow a thorough discussion of them.

The levator anguli scapulæ was absent, and in its stead, on both sides, were found separate slips passing up from the angle of the scapula to the transverse processes of the axis and atlas.

The extensor carpi radialis longior on one side had a supplementary tendon, inserted with the extensor carpi radialis brevior into the base of the third metacarpal.

The flexor sublimis digitorum had a supplementary head from the shaft of the radius and the fascia covering the flexor longus pollicis.

The extensor indicis and minimi digiti were wanting.

Palmaris longus wanting.

I am indebted to the careful dissection and zeal of my pupils, Messrs. Frederick Sohon and E. W. Day, for the materials upon which the foregoing discussion is based.

The cuts have been loaned from a forthcoming volume of Wood's "Reference Handbook," by the kindness of the editor of that valuable work.

1315 Corcoran Street, Washington, D. C.

A QUESTION OF PRIORITY CONCERNING A NEW THEORY OF THE ETIOLOGY OF CONGENITAL CLUB-FOOT.

A DISCLAIMER AND A CORRECTION.

By ROBERT WILLIAM PARKER, M.R.C.S.,

SURGEON TO THE EAST LONDON HOSPITAL FOR CHILDREN.

In The Medical Record of October 15th there is an article with the above title, to which, only after considerable hesitation, I have decided to reply. This article contains one or two insinuations as to my honesty, which I very much regret to find in such a place, and which I think are altogether unworthy of Dr. Berg's position and profession.

The tone of the paper is one of injured *amour-propre*, and this seems to depend largely on an error which I accidentally made in dates, which I very much deplore, and for which I apologize. In criticising an article by Dr. Berg, published five and a half years ago, I accidentally said that it was published *two years ago;* I ought to have said *two years* previously to my own paper on the "Pathology and Etiology of Congenital Club-foot," communicated to the Pathological Society of London, in 1884.

As to the main question referred to in Dr. Berg's article, that of *priority* concerning a new theory of the Etiology of Congenital Club-foot, let me at once disclaim any and all desire for priority as regards Dr. Berg, or any other writer who supports the "non-rotation inward of the limb" theory as the cause of congenital equino-varus. I have never done any original work on embryology, and what mention I have made of rotation of the limbs in my writings is based on the work of others. In the "original article"[1] in the *Lancet*, which has so raised Dr. Berg's ire, I should never have mentioned the word priority, had not the reviewer in the *International Journal* done so. I merely wrote that 'both Dr. Berg and I have been anticipated, more or less, by so many previous writers that we can both afford to say nothing about priority.' I fail to see how this can be interpreted into a claim on my part for priority, except by a reader who desires to pervert the meaning, and even the words, of the writer. Moreover, Dr. Berg himself writes that the view he has put forward has been "feebly advanced by some authorities from time to time." On what, then, does his claim to priority rest?

But I would further strengthen this disclaimer as to priority by frankly avowing that I do not accept the theory of "non-rotation inward of the lower extremities" as the cause of congenital club-foot. The utmost that I can allow is, that it is 'one probable factor.' I have, however, no specimens or facts to support even this much. To a certain extent this non-rotation inward of the limbs occurs in many infants without talipes, and is purely mechanical. How Dr. Berg can write that Drs. Parker and Shattock account "for the occurrence of club-foot in exactly the same manner that I do," I cannot explain on any other supposition than that Dr. Berg has not carefully studied my writings on the subject. Dr. Berg is, evidently, more concerned with dates than with any other point; for the mistake I made in speaking of his paper in Seguin's *Archives*, as having been published 'two years ago,' is characterized as an "important misstatement." I have already explained how this misstatement arose: anyone reading the several articles carefully will probably have arrived at the same conclusion. I again apologize for the error, but I scorn the insinuation "that the error was a wilful one."

I am willing to admit that a little more "scholarly exactitude" would have saved me from the error; but I feel it hard to be reproached for the want of "scholarly exactitude" by Dr. Berg, who, for the want of this same exactitude, has himself fallen into errors about as important as those of which he convicts me. Besides completely misunderstanding my views on the causation of club-foot, he misspells the name of my friend and esteemed collaborateur, Mr. S. G. Shattock, and he overlooks the fact that the *American Journal of the Medical Sciences* of July, 1886, was, after all, "at that time the *International*." I gather also that the writings of other authors have not always been perused with that "scholarly exactitude" which Dr. Berg appears to admire so much in others. On page 237 of the article in Seguin's *Archives* he says: "After an extensive search in the latest literature of the subject I found no use made of the advanced embryological knowledge to establish the etiology of talipes equino-varus. But lately, in consulting Billroth upon some other subject, I happened to turn upon the chapter on the etiology of club-foot, and found that he strongly expresses his convictions in favor of this latter theory, as explained by recent embryological data, although he does not clearly define either the theory itself or the data on which it rests." Curiously enough, the only author to whom Billroth refers by name in this connection is Eschricht, the original propounder of the non-rotation theory in its application to malposition of the abdominal limb! Although, as Dr. Berg says, "the portion of the article [by Eschricht] which refers to club-foot is only about half a column in extent," Volkmann evidently thought very highly of it, and in the *Deutsche Klinik*, 1863, speaks of the article as the 'few classic lines.' Lücke, too, mentions Eschricht's work (*Ueber den angeborenen Klumpfuss*). Whether any other of the authors quoted by Dr. Berg, in Seguin's *Archives of Medicine*, refer to Eschricht and his teachings or not, I do not remember. I think I have quoted sufficient names to warrant the statement that a little more "scholarly exactitude" would have saved Dr. Berg from the error of overlooking Eschricht's work.

I have already said that Dr. Berg cannot have read my writings on club-foot with much attention, for he appears not to have understood that I advocate essentially a mechanical causation for the great majority of cases. In his article in Seguin's *Archives* he classes me among the mechanicals (if I may coin such an expression), and goes on to argue against the insufficiency of the mechanical theories. Further on, after propounding his non-rotation inward theory, he says, "that no extraordinary amount of intra-uterine pressure is necessary to produce

[1] Quotations from Dr. Berg's writings are inclosed in double inverted commas; quotations from my own writings in single inverted commas.

this deformity, its cause being not pressure, but, as we have seen, 'a non-rotation inward, or a retarded rotation inward of the lower extremities.'" After such a statement, to argue that he and I hold "exactly the same" views on the causation of equino-varus is quite inexplicable to me. I hold that pressure, direct or indirect, on the feet is the essential cause of club-foot. "Non-rotation inward" of the extremities, if and when it occurs, is probably brought about in the same manner, and is "one probable factor," as I said in my article in the *Lancet*. I refuse to believe that non-rotation can occur as a spontaneous act; it must have some appreciable cause. Were it spontaneous, and due to inherent deficiency of developmental power, the limb would show traces of such deficiency at birth and carry the imprint thereof throughout life.

Further, in many cases of severe equino-varus, the whole limb, like the foot itself, is *inverted* (that is, rotated inward) far beyond the normal. Such cases are appropriately described as crus varum. Apart, however, from these extreme cases, as Lücke points out and lays stress upon, the inward rotation of the limb is often very marked. I have often observed this and found it an inconvenient part of the deformity, as far as treatment is concerned. Indeed, in all but a few exceptional cases, provision must be made, when ordering instruments, to secure that the feet and the limbs generally be turned outward. In other words, club-footed children, even after the club-foot has been reduced, show for many years a tendency to walk with the toes turned in; and this is unquestionably due to a congenital hyper-inversion of the club-footed limb. That the limb is occasionally in a position of rotation outward, I am willing to admit. Dr. Berg will find, however, that such a condition exists in non-club-footed infants quite as often as in those who are deformed.

For many reasons, then, I must decline to accept Dr. Berg's theory, that non-rotation or a retarded rotation inward of the limbs is the cause of congenital equino-varus. In my recently published book on club-foot[1] I have fully described my views; those who care to study this little book will see for themselves how essentially my views differ from those of Dr. Berg, and how uncalled for his suspicion that I have tried to dispute priority with him. I hope the foregoing explanation will satisfy Dr. Berg, 1st, That I have no wish to contest or claim priority with him; 2d, that I am quite ready to believe that he applied the embryological facts without knowing how nearly his own views had been expressed in the "few classic lines" by Eschricht, years previously; 3d, that these views had received careful attention at the hands of various writers; 4th, that, personally, I do not regard the theory of non-rotation as adequate to explain even congenital equino-varus (to say nothing of other forms of congenital club-foot); 5th, that the probable reason why Eschricht's views have not been more widely current is because the majority of authorities, like myself, regard them as insufficient, as but "one probable factor" it may be, which has been swallowed up in the wider and more satisfactory theory included under the term "the mechanical causation of club-foot."

In conclusion, I trust that, in any subsequent contributions to orthopedic surgery, Dr. Berg will be able to criticise his co-workers without imputing such motives as are implied in the expression, "Mr. Parker subjects himself to the risk of suspicion that the error was a wilful one."

In the Excessive Vomiting of Pregnancy Credé recommends the administration, every five minutes, of teaspoonful-doses of nourishment, preferably iced milk, the patient lying absolutely quiet and taking it through a glass tube.—*Weekly Medical Review.*

THE TUBERCULAR SYPHILIDE.[1]

By JAMES NEVINS HYDE, M.D.,

CHICAGO, ILL.

Hyperplastic evolution of the papule, besides producing the aberrations from type already described, may also result in the formation of definitely circumscribed, deeply seated, single or multiple, pea- to small egg-sized, bright-reddish or livid, solid, cutaneous, or more commonly subcutaneous, lesions, known as tubercles. These are usually late secondary, or early or late tertiary syphilitic symptoms which, in consequence of difference of involution, are divided into two classes.

The *resolutive tubercular syphilide* is characterized by: Slow evolution without marked subjective symptoms, disappearance after absorption of the plastic infiltration commonly involving the entire thickness of the derma, and the production, without previous ulceration, of an indelible scar. The lesions begin as superficial, pin-head-sized, reddish and roundish gummatous nodules, which, as they attain the larger dimensions named above, become flatter, smoother, more lustrous, and more deeply tinted. They are largely facial or cervical in situation, but may also spread over the trunk and extremities. They are often free from scales, except when seated upon the palms or soles, in which situations they may be covered with thick corneous plates beyond whose borders can be recognized a violaceous halo. These lesions may be generally disseminated, or grouped in distinctly circumscribed patches, either circular in outline or exhibiting some modification of the latter (*e.g.*, the reniform, horse-shoe shaped figure, etc.). The former are the earlier, the latter the later, of occurrence.

When facial in situation, the tubercles may spread in a fan-shaped area over the forehead, or extend over the bridge of the nose to the cheeks, assuming, as Bumstead and Taylor have graphically shown, the butterfly shape. The thinned, atrophic centre and elevated rim of the patch may be then significant.

An exaggerated grade of confluence and proliferation of these tubercles results in the hypertrophic, leontiasic, or vegetative syphiloderm. In these instances the nose, the chin, the ear, or some other part presents an enormous increase in bulk, with definitely distinguished lobules separated by furrows, the picture presented strongly resembling the elephantiasic condition. Again, a voluminous verrucous growth may spring from some portion of the scalp, and even in the end encroach upon a large part of that region, the warty mass freely projecting comb-like masses from the surface, smeared often with a puriform and offensive secretion (Framboesia syphilitica, Papilloma syphilitica, etc.).

The *ulcerative tubercular* (*tuberculo-ulcerative*) *syphilide* is a somewhat later manifestation of the disease, or one which, developing as it does rarely within a few months after the evolution of the chancre, occurs in neglected, untreated, cachectic, or so-called "galloping," cases. Here also the lesions appear upon the face, trunk, and extremities, with the general characteristics already described, but more commonly in definite groups. Instead of undergoing, however, the atrophic changes observed in the resolutive form, a portion, rarely all, of the tubercles forming the patch, soften or become covered with a greenish or blackish crust from desiccation of the ichorous or sanguinolent liquid furnished by the breaking down of the gumma, beneath which an ulcer forms somewhat larger in size than the lesions from which it sprang. In this way the face may display over the chin, forehead, or cheeks, a dense tumefaction composed of a group of closely agglomerated, livid, pea-sized papules, ulcers, and crusts, or a distinctly outlined ring of such lesions disintegrating at the periphery and surrounding an atrophic cicatricial, or even ulcerated central area. Gangrene and phagedéna very rarely complicate these de-

[1] Extract from the article Syphilis, in Wood's Reference Handbook of the Medical Sciences, vol. vi.

structive processes. The ulcers which form are of typical syphilitic aspect, with pultaceous floor, steep, "clean-cut" edges, ichorous secretion, and serpiginous tendencies.

Mixed forms of commingled resolutive and ulcerative tubercles are not rare of occurrence. The following are common clinical pictures: A patient, five to ten years after infection, has the forehead, nose, and cheeks fully covered with numerous, firm, pea-sized, smooth, shining nodules, vivid and dull-red in hue, occupying an infiltrated integument of the same general color. Some of the tubercles are slightly crust-capped, others are irregularly excavated as if wasting at such points. Between them are distinctly defined, large pin-head to pea-sized atrophic, non-pigmented depressions resembling youngish scars. These are spread with some regularity between young and mature tubercles, even at the scalp-border and among the hairs, over the tip of the nose, and well over the cheeks. Uneven and verrucous patches may indeed occupy distant portions of the scalp, where hairs have fallen from an atrophic area. Sometimes they undergo colloid degeneration. Attention is particularly directed to this complexus of nodules, crusts, atrophic disks, minute ulcers, and scanty pustules when occurring in this region, as it is a feature very rarely seen in any other disease than syphilis.

Still other symptoms are well shown in the accompanying colored plate, which admirably reproduces a colored photograph from the collection of Dr. George Henry Fox, of New York. Numerous plaques are here visible distributed over the trunk and shoulders, having the exceedingly definite and circular outline, atrophic or cicatricial centre, proliferating or disintegrating border, and characteristic tint of patches of syphilitic tubercles. At one or another point may be recognized almost all of the several changes described above. The extreme facial disfigurement produced in exceptional cases by a recurring series of these metamorphoses is shown in the accompanying illustration, executed from a photograph of one of the author's patients, who had been suffering for many years from a tubercular syphiloderm of the face.[1]

In most of these cases, the changes wrought in the course of time after the employment of an appropriate therapy are marvellous. The violaceous tint disappears; the scars, if any have resulted, are transformed into thin, superficial, uncolored, or dead-whitish, inconspicuous blemishes; the natural fat of the panniculus adiposus is restored; and, even in middle life, after the fullest grade of evolution described above has been reached in the face of a woman, a fair degree of comeliness is restored.

Lupus vulgaris is distinguished from this condition by its onset at an earlier period of life, its far narrower limitations, its greater asymmetry, its profounder and more disfiguring scars, and its much more indolent career. The tubercles of lepra producing the characteristic leontiasic aspect of the face are far more chronic in evolution, more deeply pigmented and "varnished," less often ulcerated, crusted, and commingled with scars. The pearly, milium-like nodules of epithelioma are quite unlike the tinted tubercles of syphilis, are never so numerous; and the smooth-glazed, bright-red, and scantily secreting floor of the epitheliomatous (rodent) ulcer never suggests the foul excavations of syphilis. Psoriasis is always scaly, never ulcerative in type, never crusted nor pustular. The most difficult cases for differential diagnosis are those of hypertrophic acne of the nose, with gaping orifices of sebaceous ducts whence comedo-plugs may have been expressed, interspersed between dull-reddish acne-papules. Here the history of the case, the absence of scalp-lesions, the stricter limitation of the patch to the tip and alæ of the nose, the absence of a distinct ulcer, and the conspicuously smaller size of the scar-like depressions, usually furnish a clue to the distinction sought to be established.

240 Wabash Avenue.

PAPILLOMA OF THE UVULA.

By WILLIAM FREEMAN FRENCH, A.M., M.D.,
NOROTON, CONN.

The following is the history of a case which recently occurred in my practice, and was of great interest to me, being the first of the kind I had ever seen.

T. M——, about thirty years of age, has been troubled at times, as long as he can remember, with a sore spot in his throat (although there was no pain in swallowing). This was accompanied with vomiting, whenever he passed directly from his meals to the open air, and took a long breath with his mouth open. There was also a sharp, hacking cough. The Crown Prince's case seemed to be in the patient's mind, although there was no feeling of a foreign body in the throat. On examination I found hanging from the tip of the uvula and descending to the right, a body over one inch in length, beginning with a thin pedicle and widening to the base, where it looked like a seed-wart, so called. It was about a quarter of an inch in diameter, circular in form, and flattened from before backward.

I made the diagnosis of papilloma, although to me the location was unusual. Having, after a few days, got the throat in such a condition that a free handling of the parts could be made without exciting vomiting, I took my patient to my friend Dr. Geib, of Stamford, and having thoroughly painted the uvula with a four per cent. solution of cocaine hydrochlorate, I depressed the tongue with my finger, while Dr. Geib easily snipped off the growth. The sore spot in the throat immediately vanished, and with it the irritable condition of the fauces, the vomiting, etc. The stump alone felt sore for twenty-four hours.

The location of the papilloma in this case is my only excuse for reporting it.

ANTIPYRINE IN ACUTE AND PAINFUL AFFECTIONS OF THE EYE.

By GEORGE STERLING RYERSON, M.D., C.M.,
LECTURER ON THE EYE, EAR, AND THROAT IN TRINITY MEDICAL SCHOOL, TORONTO, CANADA.

The want of some drug other than opium and its alkaloids, to control pain in acute inflammations of the eye, has long been felt. My experience with antipyrine leads me to hope that such an agent has been found. The number of cases in which I have employed it has, however, been so small that I hesitate to pronounce a definite opinion on the subject, and it is with a view of bringing the matter before the profession for a more extended trial that I have ventured to pen this note. It may be that the drug has been employed for this purpose before, but, so far as I am concerned, the discovery of the action of antipyrine in acute inflammation of the eye is original. The following are my cases:

Case I.—J. W——, fifty-eighty ears of age. August 31, 1887: Extraction of a cataract without iridectomy, acute plastic iritis. Severe pain in eye and head relieved by sedatives for a time only. As there was also some hyperexia, I bethought myself of antipyrine. I gave three doses of twenty grains each at intervals of three hours. The relief of pain was almost magical. I had no further difficulty in controlling pain, and the inflammation seemed also to decline. Six weeks later I did an iridectomy giving fair vision. No pain followed the operation.

Case II.—Mrs. K——, fifty years of age. November 17, 1887: Acute glaucoma; secondary to relapsing iritis and exclusion of the pupil. Severe pain not relieved by cocaine and eserine, and only partially by morphia. Forty grains of antipyrine in two doses, with an interval of three hours, completely relieved her.

The drug was repeated at intervals, according to the pain, for several days, when an iridectomy was performed. Patient was in very poor general health.

CASE III.—Mrs. B——, aged twenty-four. November 22, 1887: Acute iritis, one week's duration; numerous adhesions between the margin of pupil and the lens. She has had several attacks. There is no known cause. The pain, which was very severe at night, was relieved at once by twenty grains of antipyrine. The patient had been treated for twenty four hours previously with atropine without much relief to pain.

THE USES OF ANTIPYRIN OTHER THAN AS AN ANTIPYRETIC.

BY WILLIAM F. WRIGHT, M.D.,

NEW YORK.

AT the present time antipyrin is attracting considerable attention as of use in certain nervous derangements. That it has a much wider range of usefulness than is commonly supposed is evident to every practitioner who has made much use of the drug. In hemicrania, neuralgia of the trigeminum, sciatica, ovarian neuralgia, muscular rheumatism, hysterical affection, and in certain spasmodic affections, I have found it of the greatest benefit. In hemicrania, of whatever origin, I use it with far more success than I have ever had with any other drug. Given in fifteen-grain dose at the onset of an attack of migraine, it will cut short the attack, and a patient who has grown to expect from twelve to eighteen hours of agony before relief could be expected will, within an hour, be free from pain and, if reclining, will probably be sleeping quietly. Some patients carry with them constantly a powder of fifteen grains, to take upon the approach of an attack, and as yet I have not known it to fail in a single instance. In the cases frequently met with among professional men, business men, and worried, overworked mothers, where we have a cephalalgia associated with insomnia and much nervous irritability, antipyrin will be found of far more benefit than will any of the drugs commonly given. A dose of fifteen grains at bedtime will in most cases be quite sufficient, although I have sometimes found it necessary to repeat the dose in two hours. Combined with chloral, better results can be obtained than from chloral alone. In a certain number of cases of sciatica it has given great relief when taken in fifteen-grain doses three or four times daily. In antipyrin I have grown to feel that I have a weapon with which to face that hydra hysteria. The hysterical knee, hand, and convulsion will yield to antipyrin when moral suasion and all other forms of treatment have failed. About the cases of lumbago or muscular rheumatism in which I have tried antipyrin, there has been some doubt as to whether or no they were hysterical. The same can be said of the cases of ovarian neuralgia, although I have seen enough to convince me that in genuine cases it exerts some power for good.

In nystagmus, where there is neuralgia of the infra-orbital or supra-orbital nerves, it will be found of great benefit. The improvement is not so marked in cases not associated with pain. In blepharo-spasm, and the painful twitching of other sets of muscles, marked benefit is speedily derived from full doses of the drug. The spasmodic cough of children is relieved, if not cured, by small doses—from three to five grains in syrup of Tolu—repeated every two or three hours. In cases of pertussis I have not noticed much, if any, improvement from the use of antipyrin. The eruption which antipyrin sometimes causes I have seen but little of, and have seen no bad effects follow the cautious use of the drug. But in no case have I given more than fifteen grains at one dose, and this quantity I have not repeated within two hours.

57 WEST TENTH STREET.

SLOW AND RAPID HEART-BEATS.

DR. WILLIAM T. SMITH, of Hanover, N. H., referring to the case of slow heart-beat reported by Dr. Squire in THE MEDICAL RECORD for November 26th, writes: "One of my neighbors, a large, fine-looking man, eighty years of age, has a pulse which is ordinarily 28 to the minute. Ten years ago he had trouble with his heart for some months, the exact nature of which I do not know. Since that time he has had a pulse ranging between 24 and 32. The heart is hypertrophied and the arteries are hard. There is no sign of valvular lesion. I can detect no intermediate beat. He is in excellent health, with uncommon vigor for his age, and, except that he is short-breathed when he walks up-hill or makes other special exertion, shows no sign of failure of the circulatory apparatus.

"By way of contrast I will mention a woman who came under my care a few years ago, whose heart beat 225 times in a minute for two days. Of course no pulse could be counted, but, by laying my ear upon her chest, I could count the beats, which were distinct and regular. I expected speedy death, but the rate gradually diminished until one morning, about a week after the rapid action, I found it normal. The patient had a long-standing heart-trouble which we called functional, because we could recognize no organic lesion. She has since died, but an autopsy was not permitted."

GLYCOSURIA IN A YOUNG CHILD.

DR. J. F. BERG, of North Branch, N. J., reports the following case: "I was asked several weeks since to prescribe for nocturnal incontinence of urine in a boy three and a half years of age. I ordered a belladonna mixture andl eft some directions for diet, having scarcely seen the child. Last week the boy was fretful and complained of being tired. I then examined him carefully, and found a dry skin, fuzzed tongue, and a markedly distended abdomen. The child was reported to be hungry all the time, and he drank large quantities of water and milk. I ordered some calomel, thinking that it might possibly be a case of worms, and asked that the urine passed in the morning be saved for me. Examination of this urine showed a specific gravity of 1.040, and the sulphate of copper test revealed the presence of sugar. In a few days coma supervened and the little patient died. Emaciation proceeded at such a rapid rate that the child seemed literally to melt away. I wish to put the case on record as one of the few instances of diabetes mellitus at so early an age, and also that it may serve as a warning to others to make a correct diagnosis before treating such an apparently insignificant trouble as nocturnal incontinence of urine in children.

"I have failed to discover a satisfactory cause for the disease in this case. The affection dates back to the peach-season, at which time the patient ate of this fruit to his heart's content, eating, as children do, skins and all except the stone. Now it is a well-known old woman's remedy to give peach-parings, with the down or fuzz on, as a diuretic in dropsy, and I know that they act powerfully. Whether this was a factor in the causation of the disease I know not. I can only say that, if so, it is the first and only instance of the kind that has come under my observation after a residence of over twenty years in a peach-growing district. The boy was the youngest of six children, and all his brothers and sisters, as well as his parents and grandparents, are healthy."

CARE IN DIAGNOSIS.

DR. EDWARD S. BLAIR, of Sioux City, Ia., writes: "'Festina lente' is a motto which nowhere deserves more rigid observance than in the matter of diagnosis. Many a case has resulted seriously, and not a few fatally, because when the physician or surgeon was called he dismissed the patient as not deserving special care or attention. A case

of neglect of attention in diagnosis and consequent suffering illustrates the point at hand.

"A young lady, about twenty-one years of age, accidentally swallowed a pin. It lodged in a horizontal position in her throat, and, in her efforts to expel it, its position was changed so that it was held longitudinally, with the point downward. Every attempt now to expel the offending body was futile, and was attended with intense suffering. Each effort at swallowing or speaking was repaid by agonizing thrusts from the sharp-pointed intruder. All that domestic knowledge could suggest was done, but without relief. The patient sought out the best medical aid then, in a neighboring town. The man applied to was a surgeon of considerable local fame. He carelessly looked the patient over, told her there was no longer any pin there, and sent her home. She, however, knew too well the error of her adviser, and continued to feel the piercing thrusts of the pin.

"Nature now took the case in hand, but she is one of those slow, cautious operators, who strictly observes the motto quoted above—she hastens slowly. Nine long weeks, while the patient suffered almost unendurable pain, by a slow process of ulceration the little fold which held the point of the pin was made to let go its grasp, and suddenly, while the patient was stooping over, the pin dropped forward into her throat and was expelled. Old mother nature is a kind nurse and a safe operator, but a little timely assistance from the surgeon might have shortened much the period of suffering in this instance."

Progress of Medical Science.

Modern Diet and its Effects on Health.—Dr. Boyd says there are some points in connection with this subject which are not of merely professional interest, but of far wider significance, and may be regarded as of national importance also, as they embrace not only our every-day condition of health as individuals, but our very physical existence as a race (*British Medical Journal*). Foremost among these points is the question how many of our modern diseases depend upon our diet, and why dyspepsia and its concomitant troubles are so prevalent. In the consideration of this subject we might reasonably ask how much man's habits and occupation have contributed to the deterioration of his nervous and digestive powers. Where such a preponderance of albuminoids enters into our food as is at present the case, the additional use of alcohol with them becomes a necessity to aid in their digestion, more especially as from the impaired nervous energy of the present day the digestive organs require the stimulus they give to increase secretion. But is assimilation of a large quantity of albuminoids of benefit to our system at large? Having regard to the fact that the ptomaines of our food are mainly derived from albuminoids, most certainly it cannot be; and in this meat-eating country, where, from climatic influences, rheumatism and its congeners are endemic, a great liability to cardiac affections necessarily ensues. As most of the albuminoid waste passes through the kidneys, have we not a direct connection between our food and the prevalence of Bright's disease? The prevailing taste includes a large amount of animal food, and the present state of the laws allows too great facilities for all sections of society to poison themselves with this form of food. The State regulates the sale and the quality of the alcohol the public consumes, but exercises no control over the quality of the meat its people use. It is very doubtful if the opportunity to purchase meat cheaply and use it in abundance is an advantage, looking at the matter from a public health point of view. It may be said that it is not the abundant use of meat, but the manner of cooking it, that is injurious. Granted that this is so, has not the State a greater reason to attend to the wants of its people in this respect? Schools of cooking would seem, then, of paramount importance, to enable the poor to receive that instruction which is so essential to their moral and physical welfare.

Fecal Anæmia.—At a recent meeting of the London Medical Society (*The British Medical Journal*, November 19, 1887), Sir Andrew Clark read a paper on the production and treatment of anæmia and chlorosis in girls and young women from fourteen to twenty-four years of age. He had studied many years ago the results of retention of the excretions and the effects of their decomposition. He described the peculiar and characteristic symptoms of those forms of anæmia or chlorosis which occur in young women, which he ascribed in a large number of cases to the accumulation in the large intestines of fecal matter, its decomposition, and the subsequent absorption of the poisonous products so formed. He pointed out that the bowels might be open daily but imperfectly, so that even where constipation was said not to exist, fecal retention nevertheless might and did take place, with the evil results alluded to. The condition was one which was not confined to any particular class of society; it occurred in the underfed and the overfed, in the rich and the poor alike. He referred to the various theories which had been put forward with respect to the causation of anæmia by Virchow, Germain Sée, and others. Girls at puberty began to think more about their personal appearance; they ceased to take the same active exercise as before; they pinched in their waists and developed a self-consciousness in all their acts which led, *inter alia*, to their being very shy about going to the closet. He quoted the researches on the subject of the formation of alkaloids in the intestines, and urged that everything pointed to a toxic absorption. In collateral proof of his assertion he instanced the almost invariable success which attended the administration of aperient iron mixtures, which unloaded the bowels and restored things to their normal condition. He discussed the dietetic and medicinal treatment of such cases in detail, and pointed out that aperients were even more essential than ferruginous preparations. In patients who had been treated without success for months, a cure was rapidly effected if these principles were borne in mind. To maintain the cure, it was of course essential to prevent the recurrence of the condition of things which had given rise to it.

Pseudo-Hydramnios.—At a recent meeting of the British Gynecological Society (*The British Medical Journal*), Dr. J. St. Clair Boyd described a case in which the superabundance of fluid did not, as in ordinary cases of hydramnios, take origin in the membranes, but had its source in a hydrocephalic head from an aperture in which it flowed. The patient, aged forty-two, had had six children, and thought herself pregnant again, but her enormous size seemed inconsistent with that view. She was suffering from enormous abdominal distention, dyspnœa, and dropsical effusion of the lower extremities. On making a vaginal examination the os uteri was found dilated to the size of a crown-piece, and a bag of membranes protruding from it. On rupturing this thirty pints of fluid escaped. The child was subsequently delivered with the short forceps. The placenta was adherent and had to be removed. The uterus was then injected with a hot solution of hydrarg. perchlor., 1 in 2,000. No hemorrhage occurred. On the third day all trace of dropsical effusion had disappeared from the patient's lower extremities. The child, which was born at the seventh month, had an immense hydrocephalic head. The fluid apparently exuded below the occipital eminence, at which part the skin had become wrinkled, owing to its escape.

Trichinosis in Ducks.—Twenty persons in Inowraclaw, Posen, were recently attacked with symptoms of trichinosis, and an investigation showed that they were poisoned by eating the flesh of trichinous ducks.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, December 31, 1887.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

As will be seen by an item elsewhere, the work of organizing the coming Congress of American Physicians and Surgeons is progressing, and there is every promise that the meeting will be a most successful one. The idea which it is the object of the Congress to carry out is, that of bringing together those interested in special and general medical or surgical work, and of doing it in such a way that scientific work without medical politics shall be the result. To promote this end, each association preserves entirely its autonomy, and the President of the Congress is elected from each special society in turn. There are no delegates, and every member of a special association is a member of the Congress.

The plan of having such a Congress as this was suggested by Dr. Mastin, of Mobile, in May, 1886, only a year and a half ago; but its merits were so striking and obvious that it was almost immediately approved, and all of the national associations, so far as we can learn, except one, have heartily joined in it.

We feel sure that the physicians of the South, where the project was conceived, and those of the East and the West, both which sections promise to be well represented, will approve and encourage an attempt which is destined greatly to promote medical science in this country.

THE STATE BOARD OF HEALTH AND QUARANTINE.

DISCUSSIONS regarding quarantine at this port are so tinctured with political feeling that it is difficult to arrive at a fair estimate of the actual merits of the matter. On the one hand is the impregnable fact that no cholera has been brought into the country; while on the other are certain adverse reports of those more or less expert in sanitation, and the partisan onslaughts of the daily press.

The State Board of Health has taken upon itself the duty of examining and reporting to the Governor of New York upon the condition of the quarantine service at this port. This report is based chiefly upon the personal inspection of the secretary, Dr. Balch, and it contains really little more than a reiteration of the statements made by earlier inquirers. It is shown that the condition of things on Hoffman Island was decidedly bad, and that the medical attendance at Swinburne Island was insufficient. We can well remember that, some months ago, much of the blame for this was charged upon our Governor, who is a Democrat, and who vetoed the extra appropriation for improving the condition of quarantine. Now, however, the fault is laid upon the health officer of the port, who is a Republican.

The concluding paragraphs of the report show that the State Board feel very deeply on the subject. For, though it is stated at first that "the State Board of Health does not consider it within its province to pronounce upon the actions of the quarantine authorities," yet it is added immediately, "that the health of the State and the country was put in great jeopardy by the culpable unreadiness of the station admits of no question."

And it is stated also, that "it is the unanimous opinion of those posted on such matters that it would be difficult to imagine a worse state of affairs than now exists at the quarantine station. It is hard to realize, in this age of civilization, that the harbor of the city of New York should be so inadequately provided with facilities for the prevention and extinction of an epidemic."

The conclusion that we form from the facts given is that our quarantine management is by no means up to the mark, though its condition is hardly the crying disgrace which some represent it to be. The most lamentable thing about it is that it forms part of a political machine. It is the same old story which we hear in connection with our hospitals, asylums, boards of health, and quarantine. The hand of the political boss is on each one. In municipal politics everything tends to drive the doctor to "mugwumpery," by which we understand the advocacy of the management of affairs by the best men, not by the most influential partisans.

IS DIDACTIC LECTURING BEHIND THE TIMES?

THE communication from a "Medical Student," in another column, is deserving of more than a passing notice. It will doubtless receive this by its intrinsic force of putting the thing. In the main, and even more so, we quite agree with the sufferer. There is altogether too much didactic lecturing in our college courses. Lecturing is not necessarily teaching. There should be some proportion between the quantity of seed sown and the capacity of soil to take it up. Rhetorical stimulation may help somewhat, but the more frequently it is harrowed in, the sooner the responsiveness of retroactive appreciation wears out. Seven sermons daily would in the long run paralyze the staying energies of the most devout listener. But as each lecturer comes in turn freshly to his work, he goes on from day to day, throughout the course, realizing to the full how much better it is to give than to receive. As a result, the mind of his unfortunate listener becomes a compost collection of incongruous facts, with only here and there a tender blade of truth struggling to the surface of his understanding. It must be hot-bed culture, if anything; succulency rather than strength, weeds rather than fruit.

But we may be told that the abolition of the didactic lecture will alter the whole system of medical instruction. It will make no matter, however, for we are destined to come to it by and by. The clinical room is gradually growing larger by a force of its own, laboratories are winging themselves on the sides of the college buildings, because that is the only sensible way in which the latter

can spread; the wards of our hospitals are more and more frequented each year, and the practical must eventually survive the theoretical. The signs of the times are seen in the pretended prominence of clinical over didactic teaching, but the latter is destined to have a long agony of dissolution; the office of simple lecturer has been too much magnified to shrink too suddenly into insignificance. The most impregnable part of the didactic system, the one which has forced its recognition most emphatically upon the students, rests upon the ultimatum of an examination by the lecturers. How many lecturers would have full audiences if the case were otherwise, and there was an independent board of examiners?

PUTTING QUARANTINE UNDER NATIONAL CONTROL.

The College of Physicians of Philadelphia continues its praiseworthy agitation in favor of national control of quarantine. It has adopted a report addressed to the medical societies of the country and asking their cooperation in securing the proposed reform. The Committee of the College say that present methods are faulty and inadequate; that only four ports, including New York and not including Philadelphia, approximate being efficiently prepared to cope with threatened invasion by pestilence. The faults of administration, as shown in New York Harbor during the recent cholera-scare, are condemned, and the fact that local quarantine stations are dependent upon political conditions there existing for a large part of their efficiency is pointed out. The necessity of national control is urged for these reasons: It would secure uniformity o operation; the benefits of quarantine which inure to the welfare of the whole country would be under the control of the whole people, and not depend upon seaboard cities for maintenance. The report recommends legislation to organize suitable buildings and appliances at all ports under corps of trained officials of the Government, under the direction of a bureau of control at Washington attached to one of the departments of the Government. Consular reports and sanitary inspection at points of embarkation would be included in the scheme.

The attempt to remove quarantine from State and city to national control involves some very radical changes. The plan will receive lively opposition from politicians and States-rights Democrats. It cannot, in fact, be carried for a long time; meanwhile, however, some good may result from a thorough discussion and agitation of the matter

THE NEED OF AN ASYLUM FOR NARCOTIC HABITUÉS.

In a communication read before the American Association for the Cure of Inebriates on November 9, 1887, Dr. J. B. Mattison makes a forcible plea for the foundation of an institution for the reception and treatment of sufferers from the opium, chloral, or cocaine habit. He says, very justly, that general hospitals and insane asylums are not, as a rule, places where patients of this class are welcomed or where they can receive conveniently the proper treatment. There are many objections to be urged against their reception in inebriate asylums, and the expense of a stay in private institutions for the care of narcotic *habitués* is beyond the means of many of them. The writer suggests that an institution, endowed by private benefaction, be established, in which a certain number of free patients may be received, the running expenses being met by the income derived from the board and medical treatment of paying patients. Dr. Mattison's suggestion is a good one, and we hope it may be acted upon at no distant day.

News of the Week.

Dr. Samuel Ketch has been appointed visiting orthopedic surgeon to the institutions on Randall's Island.

At the Congress of American Physicians and Surgeons, to be held in Washington, September 17, 18, and 19, 1888, there will be meetings of the special associations morning and afternoon, and of the whole Congress in the evening. On September 17th there will be a discussion on intestinal obstruction in its medical and surgical aspects, and on Wednesday evening a discussion on cerebral localization; and on Thursday evening the address of the President will be delivered, followed by a reception in the Museum Building. There will be no entertainment provided in connection with the Congress.

Authors of Bacteriological Papers are requested to send their reprints to Dr. Max Toeplitz, of 67 East Fifty-ninth Street, New York City, for report in the *Centralblatt für Bacteriologie*.

Typhoid Fever in Pittsburg.—In the last three months there have been two thousand cases of typhoid fever in Pittsburg. A recent investigation by a Committee of the Board of Health shows that the water-supply is dangerously polluted by organic matter.

Increase of Heart Disease.—It is said that deaths from heart disease are six times more frequent proportionately in Boston now than thirty-five years ago.

The Late Dr. Alonzo Clark bequeathed the sum of $5,000 to Williams College.

The Hartford Hospital has received a bequest of $10,000 from the late Miss Esther Pratt.

Suit against the New York Hospital.—George W. Foulk sued the Society of the New York Hospital for $20,000 damages on account of the brutal treatment which he alleges he suffered when he was a patient in the Bloomingdale Insane Asylum last April. The case was tried in the Superior Court before Judge Dugro and a jury. After being out all night the jury came in yesterday morning, and were discharged because they were unable to agree.

Dr. Swithin Chandler, of Faulkland, Del., died on December 22d, aged fifty-seven. Dr. Chandler was for some years prominent in State politics.

Dr. G. Pomeroy, of Wayne County, N. Y., died on December 14th, aged seventy.

Adulterated Cocaine.—Recent analyses have shown that cocaine is being extensively adulterated with borax.

Dr. Arthur D. Bevan has been appointed Professor of Anatomy in Rush Medical College, and Dr. Charles T. Parkes Professor of Surgery, in place of the late Dr. Moses Gunn

National Guard Ambulance Corps.—An ambulance corps is to be established in the various regiments, batteries, and separate companies of the National Guard of New York.

Albert B. Strong, A.M., M.D., for twelve years Demonstrator of Anatomy in Rush Medical College, and Lecturer in Anatomy in the spring course, has severed all connection with the institution by resignation.

The Aniline Treatment of Phthisis.—Last spring Professor Kremianski described a new method of treating phthisis by aniline inhalations, etc. This method was very soon condemned. Professor Kremianski now publishes a long letter in which he complains bitterly that he has been misrepresented and misunderstood, and that the most influential medical journals in Russia have refused to admit papers by various observers which contained favorable reports of trials made of the treatment, while prominence has been persistently given to all unfavorable and unsuccessful cases. He also says that the bactericide treatment by no means consists merely of aniline inhalations, but that many other substances are employed, either in conjunction with aniline or without it. The detailed description of the treatment is set forth in a book by Professor Kremianski.

A New Subjective Test of Refraction.—Those who are concerned with testing refraction have occasionally felt the want of a test of ready application, which should distinguish defective vision caused by ametropia and that caused by an impairment of the light-sense. It is true that there are numerous excellent modes of estimating refraction, and some—such, for instance, as the shadow-test—are of easy application, but much time would often be saved if it could be ascertained at the outset that the impairment of vision is due to some other cause than the error of refraction. Moreover, few have sufficient confidence in their own accuracy to feel convinced that they have correctly measured a difficult astigmatism, when the correcting lenses give an unsatisfactory result. It seems to us that the test introduced by Dr. Wolffberg will, to a great extent, supply this want. It consists in instituting a comparison between the patient's power of distinguishing form, as tested by Snellen's distance-types, and his color-perception, as shown by the distance at which he can see a red and a green disk on a black ground. An error of refraction will have the greatest effect upon the form-perception, and a defect in the light-sense of the color-vision. From an examination of a large number of ametropes in whom correction gave normal vision, and of emmetropes rendered ametropic by spherical lenses, Dr. Wolffberg has constructed a table showing the distance at which the disks should be visible in each grade of impaired vision, when the impairment is solely due to an error of refraction; when the conditions correspond with the table, it may be concluded that correction of the ametropia by spherical lenses will give normal vision. Astigmatism causes a greater impairment of the form-perception without a corresponding effect on the color-perception, hence its presence is shown by the colored disks being visible at a greater distance than corresponds with the vision. A diminution in the distance at which the disks are visible shows, on the contrary, that the light-sense is impaired, and that normal vision will not be obtained by the correction of any error of refraction that may coexist. The details of the test will be found in the *Klin. Monatsbl. für Augenheilk.*, 1886, p. 359; and an important paper, showing the result of its application in a large number of cases, has just appeared in the November number of the same journal. Dr. Wolffberg thinks that the test would be equally applicable to a color-blind person, as he need not see the colors as such, but only the disk as an object. One color-blind individual was tested with an accurate result, but more evidence is required as to this.—*British Medical Journal.*

A Work of Gross Ignorance and Injustice has been done by the Philadelphia Board of Health in fining a physician $100 for not reporting to the Board two cases of leprosy under his charge. We should be glad to learn through what divine illumination the Board in question was able to say that leprosy is a contagious disease, when some of the best experts in the world are in doubt about it. Leprosy is certainly not actively nor dangerously contagious, and if we come to refinements, phthisis is a contagious disease also, and physicians may be fined whenever they fail to report chronic expectoration.

Apparent Illustrations of the Contagiousness of Cancer.—Dr. Richard Budd contributes to *The Lancet* the following: "1. Some years ago a gentleman who had spent many years in India came under my care for cancer of the lip, for which he refused to submit to any operation. When he was confined to his bed a favorite little terrier was scarcely ever out of his room, and, as is the habit of such little dogs, frequently licked his master's lips. This dog died, before his master, of cancer of the tongue. 2. A lady suffering from cancer of the uterus and vagina was nursed by a strong, healthy young woman of nineteen. She, in spite of my remonstrances, persisted in washing the rags which were saturated with the discharges from her mistress' wounds. Six months after the death of the lady this young woman was admitted into the North Devon Infirmary with a large mass of cancer in the axilla, and speedily died of the disease. 3. Since I have been in practice in this small town, five surgeons, all of whom had officiated at the North Devon Infirmary, have died of cancer. Such a mortality can hardly be conceived, except on the supposition that the disease was communicated, at least to some of them, during their manipulations on patients suffering from cancer. Dr. A. H. Clemon cites the case of a man who died from cancer of the penis, his wife having previously died of cancer of the womb."

A New Bandage for Hernia Operations.—M. Lucas-Championnière has invented a new kind of bandage for patients who have been operated on for hernia. It consists of a simple elastic band with a pad, which is placed above and not on the cicatrix.

The Childbirth Mortality in Great Britain was 4.94 in 1,000 births (1881 to 1885). In the Australian colonies it is over 6 per 1,000 births.

An Unorganized Profession.—Of the 992 registered physicians in the State of Louisiana, up to January 1, 1887, 773 are classed as regulars, and of this number only 176 are members of the Louisiana State Medical Society. Of the fifty-nine parishes of Louisiana, thirty-four (but a little more than one-half the entire number) have representatives in the State Medical Society.

A Fishy Story.—Dr. T. B. Greenley, of Hardin County, Ky., reports the case of a pregnant woman who was frightened by a fish being thrown down before her without warning. The child when born had ichthyosis. This is quite on a par with the vulgar idea that babies born under the sign of *Pisces* suffer from enuresis.

Alcohol as a Food.—Some esteemed contemporaries, with pre-glacial ideas regarding the present condition ot chemical knowledge, have asserted that alcohol is not a food. The views of competent and unbiassed persons on this point are quite settled, and the discussion of it is superfluous. The practical side, however, is shown in an interesting paragraph from an article by General Greely, in the *Forum*. He says: "The subject of alcohol was frequently and generally discussed during the winter at Cape Sabine, and all, without exception, concurred in the opinion that spirits should be taken after a day's labor was over, and not before or during exhausting work, nor while suffering from exposure that was to be continued. . . . Later, when the party had been slowly starving for many months, and when the supply of food was so diminished as to necessitate a greater reduction of rations, the pure alcohol on hand was issued as food, being diluted by about three times its weight of water. Each man received daily perhaps a quarter of an ounce of alcohol, the effect of which was most beneficial. The general impression, with which I most heartily agreed, was that the alcohol supplemented food, and had a decided alimentary value. There could be no question of its beneficial effects as a mental stimulus to every member of the party under our unfortunate condition at Sabine."

"Fecal Anæmia."—Sir Andrew Clark has a happy faculty of clapping an appropriate and suggestive name upon some well-recognized condition, and sending it out as some new parturient product in pathology. "Catheter fever" went the rounds, and finally has been accepted as a good medical expression for a veritable but venerable clinical fact. Now we learn that "fecal anæmia" is something to be recognized nosologically. Dr. Clark thinks that constipation is an important factor in producing anæmia or chlorosis in young women. The absorption of the fetid products of intestinal decomposition tend to impoverish the blood. While many plethoric people are constipated, and many anæmic people are not, it may well happen that in certain states fecal substances can be absorbed to an unusual degree, to the injury of the system. Quite independently of Sir Andrew Clark, M. Duclos, of Paris, has advanced a similar view as to the origin of chlorosis. He thinks that this disorder is a result of auto-infection, a true poisoning resulting from the retention and putrid decomposition of fecal matters in the intestine. He states that, as a rule, chlorosis is preceded by, and associated with, constipation, but this rule is not without exception. Sometimes the poisoning takes place rapidly; the putrid decomposition may be active, or the intestinal absorption may be more or less complete; and in harmony with these differences the varieties of chlorosis may be observed; even fever and endocarditis may arise as a result of such auto-infection.

Medical Women.—The *Weekly Medical Review* discourses conservatively regarding female physicians: "At present the truest, noblest life of woman is wife- and motherhood, and the stimulation of man, by her affection, to his best endeavors. When the process of evolution has so changed in its progression that man's *utriculus hominis* has developed into a childbearing uterus, and woman's *clitoris* into an organ of copulation, the time will then be ripe for an exchange of positions, but not before. 'Shoemaker, stick to your last!' And we might say: 'Woman, stick to your womanliness, the noblest quality you now possess, and the loss of which will never be compensated for as long as you are—women.'" From all which we infer that the *Review* is a secret enemy to human progress, as exemplified in colleges for educating medical women.

Obituary.

ALONZO B. PALMER, M.D.,

ANN ARBOR, MICH.

Another of the veteran leaders of the profession is gone in the person of Professor Palmer, Dean of the Medical Department of the University of Michigan, who died at Ann Arbor, Mich., on the 23d inst. He was born at Richfield, Otsego County, N. Y., October 4, 1815, and studied medicine in New York and Philadelphia. In 1852 he was chosen to the Chair of Anatomy in the Medical School of the Michigan University. Two years later he took the Chair of Materia Medica, and in 1860 he was appointed Professor of Pathology and the Practice of Medicine, which position he held continuously from that time to the present. He added to his duties others at the Berkshire Medical College, in Massachusetts, in 1864, and at Bowdoin College, Maine, in 1869. The position at the latter college he held at the time of his death.

Dr. Palmer was elected Vice-President of the American Medical Association in 1860. He was President of the United States Medical Society in 1872 and 1873, and was an honorary member of the New York and Maine Medical Societies. The University of Nashville gave him the degree of A.M. in 1855, and the Michigan University made him LL.D. Dr. Palmer was the author of an excellent treatise on the "Practice of Medicine." He was a man of strong convictions, and never knew fear in asserting them. He hated homœopathy as a pernicious and wicked system of charlatanry, fought it unsparingly, and would not exchange the commonest courtesies with its professional supporters. He hated intoxicating drink also, and by lectures and personal influence was ceaseless in his warfare against it. He was an able man, of large acquirements, and has contributed greatly to building up the Medical Department of the Michigan University. It is reported that Dr. H. F. Lyster, of Detroit, will probably be chosen his successor.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 2, 1887.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

THE OPERATION FOR DEAFNESS BY EXCISION OF THE DRUMHEAD.

DR. SAMUEL SEXTON remarked that, since presenting to the Society a case of radical cure of otorrhœa, he had operated on the ear a number of times for deafness alone. Five of his cases, where excision had been done, were present. It had long been known that persons having holes in their drumheads could still hear very well, and, indeed, in many cases better than after they healed up. A knowledge of this fact had induced Sir Astley Cooper and other surgeons of his day to endeavor to establish a permanent opening, in cases of deafness due to chronic catarrh of the middle ear, by an operation, and in the present day Kessel, Schwartze, and Lucae extended the operation to excision of the ossicles as well as the drumhead. But the results attained had never been, on the whole, encouraging.

The first case, one of sclerosis due to otitis media chronica, was operated on, November 11, 1886, for deafness in the left ear. She was twenty-seven years of age. The operation consisted in making a large opening in the posterior segment of the right drumhead and dividing the incudo-stapedial joint. To prevent reunion of the latter, the detached end of the long process of the incus was amputated. The parts healed up quickly, leaving a large opening in the drumhead through which the lower end of the long arm of the incus and the stapes could now plainly be seen. As regards the result of the operation, the patient could previously only hear shouting in right ear at twenty feet as noise; she can now hear ordinary voice beyond twenty feet.

The second case was similar to the above in respect to causation. The patient was seventeen years of age, and he had been deaf since infancy. The entire left drumhead and malleus were removed, and the incus was separated from the stapes. The parts were two months in healing, since there was a strong tendency to reproduction, and the newly developed tissues were removed, frequently as soon as formed. The result of the operation, as shown by the records, was as follows: Before excision he heard ordinary conversation—heard badly at one foot from either ear, but worst in the left; watch heard $\frac{0}{3}\frac{0}{3}$ in both. After the operation heard loud voice at twenty feet, and ordinary voice at five feet; watch, $\frac{4}{3}\frac{}{3}$. He relies entirely on the left ear now, the right ear having become gradually worse.

CASE III.—A female, eighteen years of age. Operation for the results of chronic purulent inflammation of the right middle ear, existing since childhood. She had had headaches, dizziness, and painful gatherings in the ear. The canal was occluded by a false membrane, situated about three-forty-ninths of an inch within, which was thinner in the centre, and had an opening in the lower portion the size of a pin's head. A slight purulent discharge existed. Hearing, plain ordinary voice at ten feet.

On July 7, 1887, the occluding membrane was excised, and the malleus and incus were removed. Hemorrhœa was slight. Operation lasted ten minutes.

On August 25th discharge had ceased entirely. Parts were dry, and a large and well-defined opening into the tympanum remained.

Up to the present time the general health has greatly improved. Headaches, vertigo, and pains in the ear have ceased. Patient weighed ninety-eight pounds before the operation; she now weighs one hundred and five pounds. The hearing has considerably improved. In the left ear, which is the seat of otitis media catarrhalis chronica, there is slight deafness.

CASE IV.—A female, with similar history and conditions as Case III., but came on account of deafness only. The left ear of this patient was operated on, August 4, 1887. After excision of the remains of the drumhead the malleus was extracted. Duration of operation, fifteen minutes.

This patient could not hear voice, unless almost shouted, at ten feet before the operation. She afterward heard ordinary conversation at twenty feet.

CASE V.—A domestic, thirty-two years of age. There had been a gradual loss of hearing power, on account of chronic catarrhal inflammation, for the past three years, especially in the right ear. Was obliged to give up several situations on account of this. Hearing in right ear: Ordinary voice at ten inches; loud voice at five feet; very loud voice at fifteen feet.

The drumhead and malleus of the right ear were removed on November 10, 1887. Slight local reaction. No pain, only a slight serous discharge, and a diminution of sense of taste on the right side of the tongue for a few days. Parts rapidly healed, leaving a free opening into the drum. Hearing after the operation in right ear: Ordinary voice at five feet; also at ten and twenty feet, but less accurately.

The excellent illumination under which these operations were done was furnished by a six-candle power electric light, the electro-motor power being supplied by the River & Rail Electric Company's storage battery. The delicate instruments employed were made by Mr. Ford. Ether was used in all of the cases.

The operation was without danger, and there was no pain experienced at any time. This point would scarcely deserve more than mere mention, had not such authorities as Dr. Lawrence Turnbull, of Philadelphia, and others taken pains to exclaim against operations of a like nature in purulent diseases of the ear. The German surgeons referred to before have all of them indicated the entire safety of excision, both in cases of chronic purulent and non-purulent inflammation of the middle ear.

Now that we may afford permanent passage for sound where obstruction, in cases of sclerosis of the drum, prevented its entrance, a wide field for the improvement of hearing, in certain cases otherwise irremediable, is opened up.

Dr. Sexton went on to say, from his own experience he believed that, were proper precautions observed and subsequent treatment conducted with care, the operation would be found as successful as any in the domain of surgery. The cases shown to the Society were, he believed, convincing as to this.

DR. EDWARD G. LORING made some remarks on

INFLAMMATION AS SHOWN IN THE RETINA, WITH SPECIAL REFERENCE TO DISEASE.

He first described the circulation and plasmic current in the normal eye. The first variation from the normal to which he directed attention was an *increase in the diameter of the veins*, usually uniform, but not always, and shown in all irritation or inflammations of the retina, but especially in syphilis and splenic retinitis. The increase in diameter was also accompanied, usually, by an increased length of the vessel, as shown by tortuosity. This venous dilatation was often present in the early stages of acute troubles of a general character, such as the acute stage of fever, when there was a tendency to marked congestion about the head, and when the action of the heart was full and excessive.

In some diseases of the chest—as pneumonia, pleurisy, emphysema, and asthma—the same condition of veins was present, as well as in certain forms of brain disease when the central pressure was increased, as in hydrocephalus, and in the very commencement of the disturbance of the eye dependent upon choked disk; often very use-

ful as a very early diagnostic mark in brain-disease, perhaps the first symptom noticed, and, at times, years before a general disturbance.

Enlarged veins were sometimes seen in weakened action of the heart, as if there was not force enough to drive the blood through the vessels—especially noticed in Bright's disease and many cases of profound anæmia.

Decrease in the diameter of the veins was very rare.

Dilatation of the arteries was also very rare, but when present was due to some general and remote trouble when the action was much increased.

Decrease in the diameter of the arteries occurred in the secondary stages of exhaustive diseases; marked in secondary contractions after Bright's disease, and retrogressive changes in choked disk; in debilitating diseases, as in anæmia and chlorosis.

Increase in the length of the vessels was sometimes enormous, and to what it was due was not known.

Dr. Loring then directed attention to

VARIATIONS IN THE COLOR OF THE BLOOD,

first in health and then in disease. As a rule, it was in troubles of the general system that the blood in both sets of vessels was affected. Thus all the retinal vessels were of a *darker* red in those conditions when the blood became thicker from an increase in its solid constituents, or from a removal of its fluid elements; for example, in those diseases which were accompanied by excessive discharges from the bowels, as cited by Graefe-Jäager, etc.

All the retinal vessels had a *lighter* color when the blood was deprived of its normal amount of solid constituents, or where there was a change in their conditions or proportions. Thus the blood was of a lighter color in both veins and arteries in anæmia, leucocythæmia, or whenever a condition of anæmia or hydræmia was produced.

The author of the paper then described the appearances of both sets of the retinal vessels in anæmia, sclerosis, hemorrhages, septic fever, and tubercle of the choroid.

Special mention was made of the fact that the non-detection of the tubercle-bacillus did not disprove the tubercular nature of the growths or diseased tissue in question; in two out of six cases that had been thoroughly examined the bacilli were present.

The remarks of the speaker were fully illustrated by diagrams.

Dr. Kinnicutt asked Dr. Loring in what percentage of cases of tubercular meningitis there was evidence of tubercles in the eye.

Dr. Loring said the proportion of cases in which they had been seen was very small, and he accounted for that on the ground that the ophthalmoscope was used so little in general medicine in this country.

Dr. Kinnicutt also asked if there was any other way than by the presence of tubercles discovered by ophthalmoscopic examination that tubercular meningitis could be diagnosticated by examination of the eye.

Dr. Loring thought not, unless by grave neuro-retinitis and choked disk in a child. He had seen Bright's retinitis that lasted one or two years before the suspicion was confirmed by the presence of albumen and casts in the urine. It was worthy of note that nearly all the changes in the eye in general diseases had been recognized within the last ten years.

Dr. Van Arsdale said that the arrest of circulation in the retinal vessels for two or three days, and followed by complete restoration, mentioned by Dr. Loring, found support in surgical analogy, because experimentation had demonstrated that with the use of antiseptics the fluid condition of the blood could be maintained for thirteen days without interference with the nutrition of the walls of the vessels, and then the circulation be restored completely.

Dr. Weir said that that point was borne out by the Esmarch method of treating aneurism, which produced coagulation of the blood within the vessel, that could be traced, frequently, up to the rubber band, and yet such a clot, remaining four days, had been washed away, the current re-established, and everything restored to the condition before treatment,

WITHOUT GIVING RISE TO ANY EMBOLISM WHATEVER.

Dr. J. West Roosevelt said that the cases mentioned by Dr. Loring, in which the circulation in the retina was observed to be arrested for a number of days with no bad results, that is, without the production of hemorrhages, were interesting in view of recent studies in regard to the formation of hemorrhagic infarcts. It had been proven that for the production of these lesions there must be an arrest of circulation in the terminal vessels, but that there must also be free capillary anastomosis between the vessels in which circulation is arrested and neighboring ones. The retinal vessels were terminal vessels, but as there was not such free anastomosis, arrest of the blood-current in them did not produce hemorrhage.

Dr. Weir exhibited Collins' improved

HÆMOSTATIC CLAMP,

the modification consisting in a change in the catch.

Dr. Weir also exhibited

A LITHOTRITE

submitted to Weiss by Dr. Keegen, a surgeon in India, designed especially for the performance of litholapaxy in children, and which that surgeon had used with great success. Dr. Weir did not wish to be understood as indorsing litholapaxy as a substitute for the common cutting operation for stone in the bladder in children, but he simply presented the delicately constructed instrument.

The Society then adjourned.

Ipecac in Minor Hemorrhages.—Dr. Holmes, in the *Mississippi Valley Medical Monthly*, warmly advocates the use of ipecac in all minor hemorrhages. He says that he was once asked to see a case of nose-bleeding in the person of a boy, seventeen years of age, then under the careful treatment of a competent physician. The boy was apparently healthy, but was exsanguined from the hemorrhage. He had taken ergot for eighteen hours. The doctor twice plugged the anterior and posterior nares, but, the accumulation of blood in the nose causing intense distress, the plugs were either removed or would be forced out. He then used a continuous douche of hot water for forty minutes, the water running out through the mouth, which offered only temporary encouragement and then proved ineffectual. The patient was faint and had now to maintain the recumbent posture. He was pulseless at the wrist and cold at the elbows and knees; nevertheless he got a suppository of pulv. ipecac., gr. xx., and had the ice-bag, which for some time had been applied over the head and face, placed over the epigastrium. Extreme nausea and efforts to vomit came on in about forty minutes, but at this time hemorrhage ceased. When the first paroxysms of retching were abating he took a bolus of ipecac., gr. v., without water. Thirty minutes after this dose he fell asleep, and though he was given three grains more every three hours he did not again complain of nausea or lose another drop of blood. About six weeks after, he came again with profuse epistaxis, and was at once given ten grains pulv. ipecac. and put to bed. He vomited from this dose, but was immediately given and continued to take three grains every three hours for thirteen hours. Hemorrhage ceased when emesis came on. Dr. Holmes has repeatedly used the drug in minor hemorrhage, and with far more gratifying results than from *any* thing else. In five cases of pulmonary hemorrhage he used it without failure. One of these was from a stab wound, two from lacerated injuries from broken ribs, and two from tubercular cavities.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BROWN LECTURES—TARTAR EMETIC IN CARDIAC FAILURE FROM PULMONARY CONGESTION—CANCER CAUSED BY ARSENIC—MODERN MEDICINE AND ITS RESOURCES—A NEW HYDRO THERAPEUTIC ESTABLISHMENT—AN EXTRAORDINARY CHAIN OF COINCIDENCES.

London, December 10, 1887.

The Brown Lectures at the University of London concluded this week. The fourth lecture was devoted to the important question of the prevention of hydrophobia. Professor Horsley reviewed at some length the regulations now in force in this and other countries with reference to the keeping of dogs. He remarked that the recent epidemic of hydrophobia in London had been predicted by the veterinary surgeons attached to the Brown Institution, but they had been treated as alarmists. The police regulations then brought into force, viz., the destruction of all stray dogs and the compulsory use of the muzzle for all dogs not led or carried, had quickly reduced the number of cases, and at present there were but few rabid dogs coming under observation. He spoke with approval of the proposal that all dogs should wear a collar and be registered, and recommended that dogs imported into this country should be kept under observation by a veterinary surgeon for twelve months after landing. The fifth and concluding lecture was devoted to an exposition of the curative method inaugurated by M. Pasteur.

At the last meeting of the Medical Society of London Dr. Thorowgood read an important paper on the treatment of cardiac failure in cases of pulmonary congestion and obstruction. Cardiac failure, he said, was a great cause of death in many respiratory diseases. He rather deprecated the indiscriminate employment of stimulants. He did not agree with Niemeyer that they increased pulmonary œdema, but he thought they were often given too freely and too early in the disease, to the neglect of other remedies. In cases of catarrhal pneumonia respiratory insufficiency was the principal cause of death, and too much stimulant tended to gorge the right heart with blood, and so increased the respiratory distress. While admitting the value of alcohol as a cardiac stimulant, Dr. Thorowgood considered it important in such cases to begin with such a medicine as tartarated antimony with a saline. By this plan the capillaries were relaxed, secretion promoted, and the work of the heart lessened. The principle was the same as when we sought to aid a heart failing in an attack of angina by dilating the capillaries with nitrite of amyl. Tartarated antimony seemed to leave, as Stokes, of Dublin, once said, a specific action over the capillaries of the lung. In small doses it might be stimulant, while in excessive doses it might paralyze, and so cause that congestion of the lungs which had been observed in animals poisoned by the drug. As direct respiratory stimulants, belladonna, carbonate of ammonia, and strychnia were remedies of proved and undoubted value, and the latter prevented pulmonary œdema. He objected to venesection, on the ground that its effects were only temporary.

At the Pathological Society, on the following evening, Mr. Hutchinson made a communication in which he propounded the theory that arsenic may occasionally cause cancer. He narrated several cases in which, after large doses of arsenic had been taken continuously for some time, for the cure of psoriasis, epithelial cancer had developed. He also mentioned a case in which cutaneous troubles had followed the taking of large doses of arsenic for a cancerous growth in the neck. All of which tended to show that we do not yet know all that is to be known about either arsenic or cancer.

Mr. Hutchinson's novel views did not meet with much favor from the Society. Sir James Paget, however, seemed to think there was some evidence showing that arsenic has an influence in causing cancer. As to the other point raised by Mr. Hutchinson, Dr. Hadden remarked that skin eruptions caused by arsenic are not mentioned in text-books. That may be so as regards arsenic given in ordinary medicinal doses, but both eruptions and ulcerations are on record as having been caused by chronic poisoning by arsenite of copper, details of which are to be found in works on forensic medicine.

A marked feature of the medicine of the present day is what (borrowing a term from the Church) may be termed its "broad" tendencies. It is not now considered homœopathic to order very small doses of ordinary medicines, but it is, on the contrary, freely recognized that drop-doses of vinum ipecacuanhæ (for instance) may have a very different action to that of larger doses of the same medicament, and one which we may be glad to invoke. Electricity and massage have been pressed into the service of medicine, and employed on scientific principles. We have even not been above taking a hint from the disciples of Priessnitz, and hydropathic establishments (in their modern form) are now recognized institutions. Many of them have a resident physician, and in most the "cold-water craze" has faded considerably, and warm baths given as frequently as cold ones. Many such establishments also boast of the possession of a Turkish bath. It was my privilege a few days ago to "assist" at the opening of a new institution of this kind adjoining Aldershot Camp. In addition to the methods of treatment mentioned above, it possesses a Russian vapor-bath, and also a well-arranged series of pine-baths and inhalation-rooms for carrying out a course of special treatment, as at Reichenhall and other Continental resorts. Being the only institution of its kind as yet in the United Kingdom, the Farnborough Hydro-Therapeutic Establishment has, I think, a good future before it. I had the pleasure of being seated at dinner near that distinguished physician, Dr. Hare, and heard him narrate an anecdote which is too good to be lost. A gentleman staying at an hotel in Fleet Street was (on calling for his bill) asked for the number of his room. He replied "42," whereupon another gentleman in the room asserted that to be his number. A dispute arose, which the first one thought to settle by giving his name, "Morrison." To his astonishment the other gentleman announced that as his name also. Much surprised, being strangers, the first one thought to settle the matter by giving his Christian name also, and said: "Well, my name is Samuel Morrison." "And," said his namesake, "my name is Samuel Morrison." It was at last found that one of them had mistaken the number, and the accounts were settled without further trouble, and each went on his way. The story, however, did not end here. Each of them on leaving the hotel proceeded to the house of the late Sir Thomas Watson, to consult whom he had come up expressly from the country. The whole story was then made known to Sir Thomas Watson, and from him Dr. Hare had it direct.

WHY DIDACTIC LECTURES?

To the Editor of The Medical Record.

Sir: I am attending my third course of lectures at one of your best medical schools, and as examination-time approaches I am filled, not with the febrile qualms appropriate to the season (for, judging by those who have preceded me, I don't see how I can help getting my degree), but, as I look back on my past three years of study, a question arises which perhaps your sagacity may help me to solve.

What is the real use of the *orthodox didactic lecture*? I have attended all religiously and taken notes, arguing in this way: If the lectures are worth delivering they certainly are worth noting, while, if they are of no value,

why do the professors have the effrontery to inflict them on us?

As my medical horizon widens, I begin to find that ninety-five per cent. of the sapient lore that has dropped from the oracular lips of my teachers lies between the covers of a few easily obtained, moderately expensive, English and American books and periodicals. The remaining five per cent. consists of (*a*) material too recent to have been incorporated in text-books (but, alas! the flavor of newness is not any too prominent in the average didactic lectures); (*b*) original ideas and methods (which my preceptor as often tells me are wrong as right, worthless as useful, and often designates as cranky); (*c*) flights of studied rhetoric (which are wasted on ordinary people like me); and (*d*) jokes, of which most bear such indubitable marks of age that one can only infer that they antedate modern antisepsis. Is it fair to make me spend on the average five hours a day in an uncomfortable lecture-room, listening to the often monotonous reiteration of matters of written history, ninety-five per cent., in order to get five per cent. of new facts, original ideas, oratory (*sic*) and musty *bons mots*?

Am I wrong in concluding that didactic lectures are relics of the dark ages, of times prior to the printing press?

I know that the influence of tradition is very strong among doctors, but it does not prevent them from throwing aside remedies which their predecessors considered invaluable, provided they find them worthless or get better ones. Why should it prevent them from giving up methods of instruction which are irksome and adapted to an era of literature and science long past, and to an inferior class of students which, I trust, is fast becoming extinct?

Let me ask didactic lecturers two plain questions:

Do they continue the present plan because they consider it the best? Or are they actuated by the emoluments, pecuniary (direct or indirect) or honorary, of the position?

The first question I don't believe one in ten can answer in the affirmative. That one would say that he did consider didactic lectures, properly supplemented by laboratory and clinical work, the best method of teaching medicine—very well! Does he consider them now properly supplemented? If so, why is laboratory and clinical work so held in abeyance to, so crowded out and belittled by, didactic lectures? Ordinary people, like me, are very apt to value things by the amount of cash paid for them. What must be the relative value, then, we poor students put upon clinics, which cost us nothing, laboratory work which costs us next to nothing, and didactic wind, which is forced upon us at so many cents a litre? Why are clinical teachers paid nothing, and laboratory directors and assistants next to nothing, while the didactic cormorant soars above all with the "boodle?"

I am sure that few would answer the second question in the affirmative. They would say that the pecuniary return was insignificant, while the honor of the position was more or less empty.

Now, I know that the salaries of didactic lecturers are much cut down by the expense of maintaining the school in which they teach, and I think that their net income is generally overestimated; but in the face of these facts I assert my belief, that there is not a didactic medical lecturer in New York City who does not receive, directly or indirectly, what he is satisfied to call at least a meagre pecuniary equivalent for his time and brains. It is not humanity that actuates him, nor an overweening conceit that unless the student gets second-hand wisdom from him alone he will be a failure; it is not the love of lecturing nor faith in didactic methods; but it is because it adds to his bank-account (it may be hundreds, it may be thousands), and helps to keep the wolf from the door in one case, or to maintain an empty style or luxury in another.

Alas! thus are we students made to pay a big price to keep a poor practitioner from the almshouse, or to supply a successful one with an extra servant, a third horse, or a house on Murray Hill, in order to get, in a wasteful, antiquated, and unappetizing way, a license to enter a profession for the practice of which we find ourselves, on graduating, utterly unfitted.

The remedy for this condition of things, it seems to me, is simple enough, but as it affects so many pockets it will be some time before public opinion compels its enforcement. Take away the diploma-giving, licensing power of medical schools and vest it in our already appointed State Board of Medical Examiners, a body of signal ability and impartiality. Some medical schools would at once shut their doors (no public calamity), didactic lecturers would resign by the score, and those who did not would lecture to empty benches or give more for their money. They would soon find it expedient to lay out and supervise a proper course of reading for the students, supplemented by frequent examinations, where their newly collected data and original views could be intercalated, while their flowery rhetoric and jokes could be expended at the bedside of hysterical or comatose patients.

Under this *régime* the now neglected clinical teacher and pathologist would come to the front and gather followers by the score. They could even charge fees, and

INTERNATIONAL LEGISLATION FOR THE PREVENTION OF EPIDEMICS.—At the Congress of Hygiene and Demography recently assembled in Vienna, Dr. Heirley Murphy, of London, made the following suggestions on the above subject: 1. The appointment of a sanitary authority at every port, whose duty it should be to keep itself informed as to the sanitary condition of the port, and the health of the passengers and crews of vessels arriving at or leaving the port. This information should be placed at the disposal of the consuls of the countries to which the vessels are bound. 2. Every country to have a central office, to which reports should be sent of the number of cases of specified epidemic disease occurring in every large town and port during each week, immediate notice being sent of cases of cholera. This information should also be placed at the disposal of the governments of other countries. 3. Precautions must be taken by the sanitary authorities and officers of vessels, as already indicated, to prevent the embarkation of persons or articles infected with cholera. 4. A station should be established on the Suez Canal for the purpose of obtaining information as to the health of passengers and crews of vessels bound for Europe, but not for their detention for more than the time necessary for procuring this information. 5. This information should be placed at the disposal of representatives of the different governments. 6. Every vessel arriving at a European port should be dealt with in accordance with the manner determined on by the government of that country.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 17, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	16	6
Scarlet fever	124	17
Cerebro-spinal meningitis	5	5
Measles	67	3
Diphtheria	175	60
Small-pox	3	1
Yellow fever	0	0
Cholera	0	0

TO AVOID the "drying up" effects of opium, Dr. Auld gives it in combination with ether with good results, ether being one of the most powerful secretion stimulants known. He generally prescribes equal quantities of tincture of opium and spirit of ether, and though not claiming for this a specific effect, he finds it a most useful mixture.

there were but few rabid dogs coming under observation. He spoke with approval of the proposal that all dogs should wear a collar and be registered, and recommended that dogs imported into this country should be kept under observation by a veterinary surgeon for twelve months after landing. The fifth and concluding lecture was devoted to an exposition of the curative method inaugurated by M. Pasteur.

At the last meeting of the Medical Society of London Dr. Thorowgood read an important paper on the treatment of cardiac failure in cases of pulmonary congestion and obstruction. Cardiac failure, he said, was a great cause of death in many respiratory diseases. He rather deprecated the indiscriminate employment of stimulants. He did not agree with Niemeyer that they increased pulmonary œdema, but he thought they were often given too freely and too early in the disease, to the neglect of other remedies. In cases of catarrhal pneumonia

FOR IRRIGATING THE BLADDER.—Ulzmann, of Vienna, uses exclusively the ordinary piston-syringe, believing that it enjoys the advantage of cleaning the bladder more thoroughly than do the other forms. After emptying the bladder of urine, he withdraws the catheter until the head lies in the neck of the bladder, using the internal sphincter as a valve against the eye of the instrument. The muscle thus affords no impediment to the flowing *in* of the solution, but prevents its flowing *out*. After retaining this for a longer or shorter time the patient voids the same, at the same time getting the benefit of its action upon the urethral mucous membrane.—*Medical Press of Western New York.*

SELF-TREATMENT.—There are a great many persons with whom the treatment of their own illnesses is a familiar practice. In certain cases this is, perhaps, not unjustifiable—in those, namely, where a little knowledge of medicine is found to be useful rather than dangerous in dealing with lesser ailments, and where the means of cure are commonly safe in their action, even when they fail to effect a desired result. Care must always be taken, even in such cases, to guard against mistaken application. The position of medicinal poisons for internal use is altogether different. They have no allowable place in household therapeutics. We would caution even the members of our own profession against a too great readiness to betake themselves to such means of relief, since none can gauge his own condition and its needs so accurately as a careful and intelligent outside observer, who is able to correct subjective evidence by that of skilled examination. It is much to be regretted that these considerations are apt to be regarded as unworthy of notice. General, or even a somewhat intimate, knowledge of the action of poisons is not enough to justify their use in self-treatment by persons otherwise uninstructed in medicine. The use of opium in particular is becoming much too common in the hands of others besides practitioners, and it is probable that instances in which death has thus been actually incurred bear only a very moderate proportion to those in which it has been narrowly escaped.—*The Lancet.*

THE TEACHINGS OF CREDÉ are tending toward the entire letting alone of the genitals during labor and the days succeeding it. This distinguished obstetrician, unless some abnormality presents, does not make a vaginal examination at all. His diagnosis is entirely made by external palpation and manipulation. Unless there are positive indications therefor, he teaches that for eight or nine days after labor one should neither examine, wash out, nor do anything to the genitals.—*Weekly Medical Review.*

SORE NIPPLES.—Dr. Pinard employs the following treatment with great success in cracked nipples: As soon as the cracks appear, and even as soon as the nipples become sensitive at the moment of suckling, a compress, folded in four and steeped in a solution of boric acid, is applied. The solution is of three or four per cent. Over the compress should be placed a piece of oil-silk, so as to prevent evaporation. Over the oil-silk a layer of cotton-wadding should be placed, and the whole secured by a bandage.—*American Practitioner and News.*

DR. SQUIBB ADVOCATES BUCKTHORN AS A LAXATIVE.—"In properly adjusted doses—that is, doses not too large—it is perhaps the mildest and simplest of all aperient or laxative medicines, and the easiest to adjust to a desired effect. Its operation is slow, but fairly certain, and its action continues throughout the whole tract. Rhubarb and senna affect chiefly the upper part of the tract, and have to be given in almost purgative quantities to affect the whole tract. When a mild purgative or evacuant is wanted, rhubarb and senna are better; but when a mild aperient or laxative, for delicate organisms, is wanted, buckthorn is better. When a mild degree of constipation is to be corrected, without exciting reaction and without requiring continuous medication, the buckthorn is much better, and when used with skill it seems to leave little to be desired. The dosage of buckthorn is a most important element in its proper use, and the different impressibility of different individuals to its influence makes this dosage the chief difficulty in its appropriate use. Bearing in mind that it is a simple aperient, and one slow in operation, those who use it will easily guard against giving it in too large quantities, or expecting a too prompt response to its use. Where either a very decided or very prompt response is needed, other agents are better. The limit of its use in this direction seems to be a fluid drachm of the fluid extract at bedtime where a temporary costiveness—not constipation—is to be relieved during the forepart of the following day. When temporary costiveness has passed into habitual constipation, twenty minims in a little water, one, two, or three times a day, is a better dosage, with the expectation of a partial improvement on the second or third day, when the number of doses are to be diminished. With a numerous class of delicate and sensitive women such a treatment will be generally successful, the management being easily varied to suit the conditions. Adult men of inferior impressibility will, of course, require larger quantities, but the character and the appropriate uses of the agent will always limit the dose to about one or two fluid drachms, and make it better to repeat the doses than increase the quantity at one dose. The extract is given in pill or capsule, and four to five grains is generally an effective dose if given at bedtime for two or three days."—*Ephemeris.*

Burnett, Dr. Swan M., etiology of squint, 617.
Burns, 485; a new mode of treating, 218, 722.
Burrall, Dr. F. A., visions benefited by sodium hypophosphite, 130.
Butler, Dr. John S., book notice, 257.

C

Cachexia strumipriva, 548.
Cady, Dr. N. W., tampons, 75
Cæsarean section, 192, 332, 355, 547, 767.
Caffeine and cocaine, antagonism of, 136.
Calcium phosphate in tubercular joint-disease, 159.
Calculus, renal, 216, 283, 740; urethro-vesical, 718; vesical, 59, 76, 761; vesical, in Syria, 392.
Calnek, Dr. T. M., urethral sound for applying cocaine, 679.
Calomel in certain diseases of children, 646; so called antiseptic action of, 341.
Cammann, Dr. D. M., terebene in diseases of the lungs, 476.
Cancer, and the carbonate of lime, 232; bacillus of, 59, 767, 798; Chian turpentine in, 76; contagiousness of, 580, 741; etiology of, 746; of the bladder, 82; of the bronchial glands and lung, 217; of the larynx, 677, 654, 682, 804; of the œsophagus, 585; of the stomach, 36; of the stomach without symptoms, 638; of the uterus, 325, 353, 384, 539; Paget on, 749.
Canfield, Dr. W. B., chronic endarteritis, 481.
Cannabis indica in diarrhœa, 488.
Cannon-ball in therapeutics, 627.
Carbuncle, carbolic-acid injections in the treatment of, 188.
Caries, spinal, 65.
Carnochan, Dr. John Murray, notice of death of, 602.
Case, Dr. Meigs, nerve influence in pathology, 724.
Casein as an emulsive of castor-oil, 248.
Castle, Dr. F. A., aiding the Board of Health, 664.
Castor-oil, 248, 752, 807.
Cataract, extraction, 335; extraction with and without iridectomy, 167; extraction with irrigation, 172; operations without iridectomy, 554.
Cataracts, new after-treatment, 132.
Catarrh, chronic aural, 466; nasal, resorcin in, 340; of the bladder, 723.
Catheterization in women, 131.
Cauldwell, Dr. Charles M., terebene in pulmonary affections, 583.
Caustic paste, 570.
Cephalalgia, and pharyngitis, 807.
Cerebro-spinal fever, 42.
Cerebrum, gray matter of, 306.
Cervix uteri, cancerous degeneration of the glands of, 350; carcinoma of, 539; lacerations of, 351; rapid dilatation of, 326.
Chamberlain, Dr. William M., notice of death of, 602; resolutions, 686.
Chancre, soft, iodoform pencils in, 155.
Chapin, Dr. Amory, cocaine hallucination, 570.
Chapin, Dr. Henry Dwight, predisposing causes of disease in early life, 561.
Chappell, Dr. W. F., fracture and dislocation at the elbow, 190; submucous injections in chronic throat and nasal diseases, 535.
Charcot and Vulpian, 54.
Charlesworth, Dr. G. J., intestinal obstruction, 640.
Charpentier, Dr. A., book notice, 688.
Charteris, Dr. M., book notice, 631.
Chemistry and pathology, 668.
Childbed, the diet of, 136.
Childbirth and hypnotism, 193.
Childhood, hysterical spasmodic disorders of, 717.
Children, central irritation in, 306; diseases of, 353, 375; precocious, 527; rate of growth of, 317; should they eat meat? 600.
Chisholm, Dr. Isaac W., fracture of the spine, 782.
Clinic, 348.
Chloroform and ether, 62.
Chlorosis, pigmentation of the skin of phalanges in, 365.
Cholecystenterostomy, 627.
Cholecystotomy, 547.
Cholera, 484, 574; and cold weather, 639; and quarantine, 659; bacillus of, 612; cold in treatment of, 580; new test for the bacillus, 460.
Cholera infantum, 366.
Chorea, 164, 717; abnormal, 116; cardiac relation of, 571; laryngis, 381; physostigmine in, 257.
Choreas, the diagnosis of, 599.
"Christian science," 472.
"Christian scientists," 556.
Chromidrosis, 578.
Cigarette-smoking, fatal result of, 713.
Cinchona, Louis XIV. and his dose, 230.
Cinchonidin, 192.
Cirrhosis, acute hepatic, 509; in children, 571; non-alcoholic, 283; of the liver, 457.
Civilization, price of, 472.
City doctor's summer practice, 20.
Claiborne, Dr. J. Herbert, gleditschine, 601; new local anæsthetic, 127; retinoscopy, 587; stenocarpine, 445.
Clark, Alonzo, M.D., LL.D., obituary, 414; the late Professor Alonzo, 432, 492; memorial, 691.
Clark, Dr. W. Bruce, book notice, 197.
Clay, Dr. John, Chian turpentine in cancer, 76.
Cleveland, Dr. Clement, self-retaining speculum, 34.
Climate, artificial, 348; meteorological elements of, 298; of Albuquerque, 185.
Climatology, 298, 314, 383, 405.
Clitoris, ligature of, in a young child, 624.
Club-foot, 694; congenital, 397, 811; etiology of congenital, 509.
Cobra, poison of, 408.
Cocaine, 274; and caffeine, antagonism of, 136; and tetanus, 157; applied to stricture, 679; as an aid to diagnosis in neuralgia and neuritis, 17; as an anti-emetic in yellow fever, 678; hallucination, 570; in dysuria from stricture, 485; in tonsillitis, 455; tests for the purity of, 44.
Coccyx, fracture of, 762.
Coe, Dr. Henry C., chronic pyelitis, 505; congestion of the brain following removal of the uterine appendages, 417.
Cold, in the treatment of neuralgia, 165. methods of applying, 494.
Colds, treatment of, 191.
Colic, hepatic, dioscorine in, 126; in infants 488.
College of Physicians and Surgeons, 489, 490; alumni prize of, 23.
Colleges in good standing, 575.
Colon, tumor of, 156.
Colorado Springs and Davos-Platz as winter health-resorts, 567, 577.
Colors, dread of, 737.
Colotomy, 324; inguinal, 547.
Coma, 245.
Combustion, a case of, 188.
Comedo, double, 380.
Comegys, Dr. E. G., cool bathing in inflammatory bowel affections in children, 188.
Congestion, hepatic, 671.
Congress of American Physicians and Surgeons, 602.
Conjunctiva, hemorrhage from, 213.
Consumption, pulmonary, 563.
Contagion, 541.
Continence, 500.
Contractured tissues, section of, 398.
Convulsions, puerperal, 276, 544.
Cook County Hospital, 611.
Copeland, Dr. W. P., gaseous enemata in intestinal obstruction, 155.
Coprolalia, 116, 579.
Coracoid process, fracture of, 719.
Cord, fragility of the umbilical, 623, 762; rupture of, 762; spinal hemorrhage into, 777; surgical operations upon the, 81.
Cords, tension of, 403.
Cornea, abscess from jequirity, 399; opacities of the, 64.
Coryza, acute, 625.
Couch, Dr. Louis B., ivy-poisoning, 486.
Coues, Dr. Elliott, neuro-myology, 93, 121.
Cough, barking, 116; dry, apomorphine in, 572.
Country doctors and their methods, 118.
Cousins, intermarriage of, 604.
Cow's milk, 317.
Cranium, foreign body entering cavity of, through the orbit, 82.
Creasote in phthisis, 176.
Cremation, 799; in Brazil, 221; in Paris, 582.
Creolin, 561.
Criminal, the gait of a, 278.
Crothers, Dr. T. D., mania and inebriety, 421.
Croup, an unusual case of, 678; Chinese remedy for, 752; prophylaxis, 157; wiping out the larynx in, 75.
Crown Prince of Germany, 50, 54, 140, 160, 542, 628, 654, 657, 684, 715, 743, 798.
Crutch, ischiatic, 57.
Cummins, Dr. T. J., climate of Albuquerque, 185.
Curette, uterine, 357; use of after labor, 708.
Cutler, Dr. Condict W., book notice, 56.
Cutler, Dr. J. W., indigo in amenorrhœa, 640.
Cyclopædia of Obstetrics and Gynecology, book notice, 716.
Cystitis, 494, 752; in women, 406.
Cystocolpocele, 435.
Cysts, abdominal, 59; mesenteric, 426; uterine and pelvic abscess, 425.

D

Dalby, William B., book notice, 55.
Dana, Dr. C. L., progressive spastic ataxia, 1.
Darby, John, Esq., book notice, 629.
Davis, Dr. G. W., the question of operation in perityphlitis, 133.
Deaf-mutism, 144, 514.

Deafness, a new instrument for the relief of, 148; cerebro-spinal fever as a cause of, 333.
Death, intra-uterine, 108; signs of, 578.
Death-penalty, infliction of, 111.
Death-rate, 258.
DeBlois, Dr. T. A., submucous injections, 778.
DeGarmo, Dr. W. B., mechanical treatment of spinal irritation, 790.
Decapitation, physiology of, 542.
Deformities of the lower extremities, 778; osteoclasis for the correction of, 704.
Delamere, Dr. H. S., pichi in vesical catarrh, 623.
Delirium, acute or grave, 164.
Delusions, the religious, of the insane, 304.
Demography, 298, 314.
Dengue in Syria, 328.

Dental fibril, 349.
Dentine protective, 349.
Dentition, in etiology of convulsive disorders of childhood, 717; late, 229.
Dermatitis gangrenosa infantum, 248.
Dermatology, 291, 328, 344, 360, 379, 401.
Dermatoses from emotion, 680.
Dermoid cyst, by inclusion, 202; retro-rectal, 680.
Diabetes, 367, 686; in early life, 248.
Diagnosis, care in, 814.
Diaphragm, spasm of, 635; the action of, 232.
Diarrhœa, camp, 371; cannabis indica in, 488; injection of carbolized water in, 410; summer, 45; summer, bacteria in, 354; summer, sepsis and antisepsis in, 185.
Didactic lecturing, is it behind the times? 816.
Diet in disease, 484; in health, 815.
Dietetics in mental diseases, 682.
Digestion, 779; influence of tea, coffee, and cocoa on, 287.
Digitalis, the supremacy of, 279.
Dioscorine in hepatic colic, 126.
Dioxide of hydrogen, 182.
Diphtheria, 114, 308, 317, 391, 575; and alcohol, 496; iron and potash in, 627; turpentine in, 784.
Disease, connected with intemperance, 285; in early life, 566; natural history of, 346; possibly a new one, 219.
Diseases of children, 306, 317, 353, 375, 397.
Diseases of women, pathogenesis of, 369.
Disinfectants, 658.
Dislocation, compound, of radius and ulna, 57; of the eyeball, 247; of the radius and ulna, backward, 190.
Dispensaries, new, in New York, 766.
Dispensary, an itinerant, 230.
Dispensatory, the National, book notice, 198.
Dissecting-room offal, 342.
Dissection, 27.
Distin-Maddick, Dr. E., book notice, 632.
Distrophy of the face and head, 162.
Doctor's gig, 542.
Doctors', quarrels, cure for, 48; summer practice, 33.
Dodge, Dr. W. T., nutmeg-poisoning, 624; persistent vomiting after labor, 794.
Donaldson, Dr. F., Jr., book notice, 256.
Dosometric medicine, 20.
Douche, intra-uterine, 357; intra-uterine, after labor, 708.
Drainage, after laparotomy, 436, 465; of the bladder, kidneys, and uterus through the vagina, 296.
Dressing, new impervious, 422
Dropsy, treated by permanent baths, 215.
Drowsiness and dyspepsia, 134
Drug eruptions, nomenclature of, 79.
Drugs, action of, in gastric movements, 120; adulteration of, 80; maximal doses of, 409; the use of increasing doses, 231.
Druitt's vade mecum, notice of, 629.
Drumhead, excision of, for deafness, 820.
Dulles, Dr. Charles W., hydrophobia, 671.
Dümling, Dr. H., book notice, 56, 199.
Dupon, Dr. S. F., permanganate of potassium in venomous bites of reptiles and insects, 486.
Dupuytren's contraction, 579, 606.
Durham, Dr. G. W., a new local anæsthetic, 444.
Dysacusis, 444.
Dysentery, camp, 371; etiology of, 433.
Dyspnœa, 635; of asthma, 538.
Dyspepsia, and drowsiness, 134; flatulent, 752.
Dyspepsia, infantile, 415.
Dyspepsia, motor, 194.
Dyspeptic, prayer for, 472.
Dystocia from rigid cervix, 397.
Dysuria, due to stricture, 485.

E

Ear, affections of the middle and the labyrinth, 142; bacteriology of furuncles of, 302; desquamative inflammation of, 143; disease and cerebral abscess, 137; disease of the middle, 302; effect of high atmospheric pressure on, 732; excision of the ossicles for chronic purulent inflammation, 144; nasal difficulties in diseases of, 497; peculiarities of, in the negro, 333; suppurative disease of the middle, 333; syphilitic disease of the labyrinth, 145; treatment of purulent inflammation of the middle, 25.
Echinococcus cysts, 690.
Echolalia, 579.
Eclampsia, puerperal, 276, 395, 440.
Eczema, seborrhœal, 379.
Effusion, pleural, 285.
Ehinger, Dr. C. E., book notice, 257.
Elbow, dislocation of, 495; resection of, 610.
Electrodes, intra-laryngeal, 664.
Electric-wires, stunning and burning from, 64.
Electricity, and the death penalty, 472; in treatment of uterine fibroids, 177, 754.
Electrolysis in uterine fibroids, 438.
Eliot, Dr. Llewellyn, persistent vomiting in labor, 422.
Embolism, pulmonary, occurring during gestation, 653.
Embolus of the central retinal artery, 171.
Emfield, Dr. Charles, one of the emergencies, 247.
Empyema, irrigation of the cavity in, 132; stopcock, 227.
Endarteritis, chronic, 481.
Endocarditis, septic, 772; malignant, simulating intermittent fever, 131.
Endometrium in diseases of the uterine appendages, 539.
Enema lesions, 692.
Enemata, gaseous, in the last century, 192; in intestinal obstruction, 155.
Enteritis, membranous, 556, 599.
Enterectomy, 295.
Enterorrhaphy, 295.
Entropion, 342.
Enuresis, naphthol in the treatment of, 132.
Ephedrin, 584.
Epidemics, prevention of, 823.
Epiglottis, action of, in swallowing, 403.
Epilepsy, and syphilis, 359; traumatic, 284.
Epistaxis, 31, 51, 321; and hypertrophy of the tonsils, 248; and the liver, 461, 762; the prophylactic significance of, 195.
Epithelioma, carbolic acid in, 767; of the face, 528; of the umbilicus, 246; primary, of the conjunctiva, 224; in infants, 618.
Ergot, in ophthalmic practice, 377; in treatment of uterine fibroids, 29.
Erwin, Dr. R. W., epistaxis with hypertrophied tonsils, 248.
Erysipelas, and ichthyol, 681; in infants, 618; metastasis in, 77; primary, of the larynx, 354.
Esch, Dr. J. P., irrigation of the pleural cavity in empyema, 132.
Eserine, overdose of, 92.
Ether, and chloroform, 62; death from cerebral embolism, 490; death under, 279; the dangers of, 194.
Ether-inhaler, a folding Allis, 34.
Ethylene, chloride of, 744.
Eucalyptol, subcutaneous use of, 23.
Ewald, Dr. C. A., book notice, 255.
Excision, 372; of the ankle-joint, 511, 583; of the larynx, 714.
Exhibitionists, 249.
Exostosis of the external auditory canal, 141; of the orbit, 58.
Eye, anomalies of visual apparatus, 291; antipyrin in painful affections of, 813; evisceration and the artificial vitreous, 378; faulty movements of, 345; hot water in diseases of, 309; insufficiency of muscles of, 343, 775, 805; microbes in diseases of, 326; of the adult imbecile, 170; paralysis of muscles of passive motion in the treatment of, 151; phenomenal pulsation of the interior, 170.
Eyeball, dislocation of, 247.
Eye diseases, 561.
Eyes, convergence of, 579.
Eye troubles in their relation to occipital disease, 309.

F

Face, foreign bodies in, 231; ulcers of, 528.
Fagge, Dr. Charles Hilton, book notice, 716.
Faith-cure, made insane by, 712.
Fatigue, the physiology of, 231.
Felon, how to open, 427.
Femur, bony union of the neck within the capsule, 370; fracture of, 175; gun-shot fracture of, 372; intracapsular fracture of the neck of, 638; pubic dislocation of, 132.
Fever, causes, etc., 311; cerebro-spinal, 42; cerebro-spinal, as a cause of deafness, 333; intermittent, lemons in, 485; malarial, picrate of ammonia in, 33; puerperal, 356, 357, 520, 522, 523; recurrent chronic, 544, 738; scarlet, bacillus of, 20; contagium of, 413, 737; purpura hemorrhagica following, 486; sweating, 708; Texas, specific germ of, 543; typhoid, 469, 471, 495, 580; as a cause of cardiac and arterial disease, 765; bowel lesion in, 146; inoculation against, 709; in puerperal women, 373; jaundice in, 534; naphthalin and calomel in, 797; thallin in, 157; vaccination against, 412; yellow, 293, 365; pilocarpin in, 484.
Fibroids, uterine, 438, 754; and electricity, 350; of the abdominal wall, 703; nasal, 381.
Field, Dr. Henry M., book notice, 254.
Finger, broken, 778.
Finlayson, Dr. James, book notice, 197.
Finley, Dr. Mary J., mind-cure, 590.
Fischer, Dr. Frederick L., death notice, 139.
Fischer, Dr. Louis, correspondence, 721.
Fisher, Dr. Harris, epistaxis and the liver, 762.
Fisk, Dr. Samuel A., arterial murmur, 794.
Fistula, anal, 211; rectal, 455; urinary, 291.
Fitch, Dr. W. H., typhoid fever, 469.
Food, adulterations, book notice, 197; quantity consumed by one person, 752; inspection and supply, 659; natural and artificial infants', 413.

Thermometer, a new form, 148.
Thigh, fracture of, 175.
Thrombosis of the right auricle, 203.
Thymol, medical uses of, 158.
Tibia, compound fracture of, 57.
Tic convulsif, 717.
Tobacco, deleterious effect of, on the throat and nose, 382; smoke, peculiar effect of, 722
Toledo Medical College, 686.
Tongue, peculiar condition of, 487; tonsil of, 757.
Tonsil, Luschka's, 276; pharyngeal, 751, 757.
Tonsillitis, cocaine in, 455.
Tonsils, hypertrophy of, epistaxis associated with, 248; ignipuncture of, 307.
Toothache, 808.
Tracheotomy, 382; statistics of, 752.
Trachoma-forceps, 443.
Tracy, Dr. J. L., Reynaud's disease, 793.
"Transformismus," 516.
Transfusion, 201, 202.
Tremor, hereditary, 163, 571.
Trephining, 162; antiquity of, 92; in mastoid disease, 549; in traumatic epilepsy, 284.
Trichiasis, 342.
Trichinosis, in ducks, 815.
Trimethyl carbinol, 221.
Tubal disease, 470.
Tubercle bacilli, rapid staining of, 43; localized, 22; spread of bacilli by flies, 625.
Tubercular syphilide, 812.
Tuberculosis, general, 83, 115; in man and animals, 800; localized, 426; miliary, 113; of the brain, 607; of the larynx, 30, 337; treatment of localized, 230.
Tumors, erectile, treated by electrolysis, 353; melanotic, 410; sterility of, 657.
Turnbull, Laurence, book notice, 55.
Turpentine, Chian, in cancer, 76.
Tympanum, suppuration of, 142.
Tyrrell, Dr. G. G., book notice, 253.

U

Ulcer, rodent, of the face, 528.
"Ulceration" of the cervix, 297.
Ulcers, chronic leg, 19.
Ulna, dislocation of, 57; fracture of the coronoid process of, 190.
Umbilical cord, fragility of, 456.
Umbilicus, epithelioma of, 246.
Uræmia, 332.
Urethra, double, in the male, 640; indiscriminate cutting of, 60; micro-organisms in, 598; stricture of, in a new-born child, 737.
Urethrotomy, and melancholia, 752; death from internal, 33; external, 566.
Uric acid and headache, 51.
Urine, acetone and diacetic acid in, 596; analysis of, book notice, 254; guide to analysis of, 687; micro-organisms in, 598; microscopic examination, 18; non-febrile pathological, 679; of different animals, 471; staining of, by picrate of ammonia, 231; sugar in the, 605.
Urobiline, 456.
Urobilinuria, 625.
Uterus, ablation of, after inversion, 191; carcinoma of, 325, 516; total extirpation for cancer of, 384; changes in the shape of, 325; contractions of, throughout pregnancy, 300; displacement of, 434; expulsion of, during labor, 92; fibroids of, 230; and electricity, 177, 350, 525; hemorrhages from the unimpregnated, 540; hemorrhagic condition of, 437; inflammation of the lining membrane of, 351; internal medication of, 135; rapid dilatation of the cervix, 326; removal of, with fibroid and appendages, 448; ruptured, 287; treatment of cervix during pregnancy, 356.
Uvula, papilloma of, 813.
Uvulotomy, secondary hemorrhage after, 189.

V

Vaccination, 612; and Pasteur's method, 331; and variola, 292; from the buffalo, 686; history of, in America, 655; preventive power of, 330.
Vagina, absence of, 190; blue color of, in pregnancy, 277.
Varick, Dr. Theodore R., notice of death of, 715; resolutions, 780.
Varicocele, 538; radical cure of, 676.
Variola and vaccination, 292.
Veins, varicose, abnormally located, 425.
Venereal disease, fee for treating, 219, 458, 500.
Veratrum viride, 732.
Vertebræ, fracture of the cervical, 772.
Vertigo, due to chronic aural catarrh, 466; nasal, 229.
Veterinarians, fees of, 176.
Veterinary Medical Association, 431.
Vichy and its mineral waters, 468.
Virchow's address, 516.
Visions benefited by sodium hypophosphite, 130.
Visual axis, abnormalities of, 344.
Vital statistics and pensions, 337.
Volvulus, 295.
Volkmann's antiseptic liquid, 749.
Vomiting, centre, 681; hyper-acid, 572; persistent, of labor, 422, 794; in phthisis, 247.
Von Wedekind, Dr. Lute L., a point worth knowing, 245.

W

Wagner, Dr. Clinton, winter health-resorts, 567, 577.
Wainwright, Dr. J. B., staining of urine by picrate of ammonia, 231.
